

was given in decreasing doses of 6 g., 5 g., 4 g. and 3 g. respectively for four days, making a total of 19 g. Results were very unsatisfactory, and figures corresponded to those of Lieut-Col Campbell, approximately 25% responded, and a number of these relapsed. The cases which did not respond were very resistant to treatment.

A number of cases were treated with higher concentrations of the drug and 25 g. were given. Again many cases were resistant to treatment, and gonococci were still seen after the course. I regret that no comparison was kept using the T.A.B. pyrexial therapy.

It would appear that the tablet treatment for gonorrhoea is not all that has been expected of it. Institutional pyrexial therapy proved very successful in East Africa. A point worthy of consideration is that different strains of gonococci may occur in Ceylon which are more virulent to the urethra of a large male population suddenly transplanted some thousands of miles from their own environment—I am, etc.,

S. D. N. SHAW
Capt. R.A.M.C.

Sulphonamide-resistant Gonococci

SIR—I have read with interest Lieut Col D. J. Campbell's article on gonorrhoea in North Africa and the Central Mediterranean (July 8, p. 44). I met with similar conditions when I was in charge of the Merchant Seamen's Venereal Disease Clinic in Freetown throughout 1942 and during the first nine months of 1943. The majority of the infections had been obtained in ports on the east coast of South America and the west coast of Africa. Before their arrival in Freetown many of the patients had been treated with varying doses of, usually, sulphapyridine by the ships' officers of ships carrying no surgeon. The majority of the courses of treatment were inadequate in dosage and extended over too long a period. However, there was no doubt that the gonococci were resistant to sulphapyridine and sulphathiazole. Arthritic complications were uncommon. I never saw, and epididymitis was not uncommon. A profuse urethritis and a prostatitis were present in almost every patient. My opinion, which was shared by others, was that a sulphonamide-resistant strain of gonococcus was being rapidly spread by war conditions. The reasons for the strain being resistant to the sulphonamides were not clear, but possibly it was partly due to the abuse of this class of drug—I am, etc.,

ATHOL J. JOHNSON
Medical Officer, Sierra Leone Colonial Medical Service

Aetiology of Mandibular Osteomyelitis

SIR—Mr Rainsford Mowlem in his excellent article (April 15, p. 517) discusses the role of vascular supply in the aetiology of osteomyelitis of the mandible. Mr Mowlem is referred to two articles on the subject: (1) Miltner and Wolfe, J. J., *Surgery, Gynaecology and Obstetrics* Aug., 1935, (2) Wolfe, J. J., *Chinese Medical Journal* July, 1936. These articles were based on a large series of cases seen at the Peking Union Medical College and upon experimental work done at the same institution.

The disease arose from infection about an impacted third molar unusually common among these people. It arose spontaneously—that is, none had had extraction of the tooth at the time of admission to hospital. The signs on admission were besides swelling of the tissue and fever, (1) loosening of the teeth as far as and including the first premolars, (2) hypoaesthesia of the lip. This latter sign was found long before bony changes were demonstrable by X-rays, and could have been caused only by pressure in the mandibular canal.

At operation involvement of bone was seen to extend as far as the mental foramen, the site at which anastomosis with the mandibular artery occurs. Usually the external plate only was involved, but when pus had burrowed under the periosteum of the internal plate this latter also was involved. Operation consisted in removal of the entire outer cortex, removal of the involved teeth, suturing of the gum margins, and packing the wound wide open. Interdental splinting of the jaws was done as a precautionary measure.

Experiments on dogs were divided into two series. In one the external periosteum was stripped from the bone and a cotton saturated culture of mixed staphylococcus, *Streptococcus haemolyticus* and *viduus* was packed between the periosteum and the bone. None of these animals developed osteomyelitis. In the second group the pulp chamber of the last molar tooth was opened widely. Through the root canal, which in dogs communicates freely with the mandibular canal, a pledget of cotton saturated with a similar culture of organisms as above noted was packed well down into the mandibular canal. Most of these animals developed osteomyelitis with bone involvement similar in every way to the disease in man. Thrombosis of the mandibular vessels was always present in these animals.

It was concluded that invasion of the mandibular canal and thrombosis of the mandibular vessels were the essential factors in the pathogenesis of mandibular osteomyelitis. The use of penicillin post-operatively as described by Mr Mowlem is a valuable addition to the method of treatment—I am, etc.,

Major Medical Corps U.S. Army

Timing of Schafer's Method

SIR—A visit to a military hospital, where the registrar kindly provided me with copies of *Amendments to R.A.M.C. Training* 1935 cleared up the question of the timing of Schafer's method therein given. Before Aug. 1940, the timing given was exactly as quoted in my letter of July 8 (p. 57). Brought out in Aug. 1940 *Amendments No. 6* altered the timing, making it identical with that given in *First Aid to the Injured* and the Royal Life Saving Society's booklet. Dr Samuel Hales (Aug. 12, p. 224) is therefore correct, for uniformity does now exist and my letter of July 8 loses its point. Anyone ordering a copy of *R.A.M.C. Training* 1935, would be wise at the same time to order copies of all the *Amendments*, since these apparently are not otherwise provided.

By some confusion of thought Dr Samuel Hales describes my accurate quotation as 'misleading'. What really is misleading is the existence of different copies of the same manual some giving one timing and some the other. The reason for this is now clear. There must be hundreds of copies printed before Aug. 1940 in use for Home Guard training etc., and many others besides myself must have been misled. This correspondence should certainly help to clear up 'the erroneous impression which has been created'—I am, etc.

Crowthorne, Berks.

E. F. CHAPMAN

Ascorbic Acid in Gingivitis

SIR—In the article by Stamm, Macrae, and Yudkin on the value of ascorbic acid in the treatment of gingivitis (Aug. 19, p. 239) they describe how the patients chew the tablets. Of course in spite of the N.C.O.s they get little or no ascorbic acid. The tablets are ground to a fine state the acid comes into intimate contact with the O_2 of the air, and, being a strong reducing agent, is immediately oxidized. It is not sufficient to administer a therapeutic agent, it must be shown to be absorbed, and there are other factors, even if the tablets are swallowed whole, which interfere with its absorption—e.g., the pH of the gut and the presence of tannic acid from tea or coffee. Therefore, until its absorption is proved there are no grounds for claiming that it is useless (McMillan and Inglis, *ibid.*, p. 233 and annotation on dehydration)—I am, etc.,

E. P. EVANS

Lay Psychotherapy

SIR—Your correspondent the Rev Horace Dowling has called attention (Aug. 12, p. 225) to the apprehension naturally felt by many members of the general public as to the dangers of psychotherapy when administered by untrained personnel. But he appears to fall into the error commonly assumed by all those outside the medical profession that the magic letters after a doctor's name confer magic powers, and that all that a doctor says or does is good. But doctors themselves would be among the first to agree that in the training of the ordinary medical student who later graduates into the ordinary family

ment in favour of the rejection or early elimination of the vulnerable. There is no doubt whatever that those who do succumb show a high concentration of certain ominous points, such as a poor work record, compared with those who do not. According to certain investigations that have been made in the Navy, the proportion showing these ominous points amounted (with the technique used) to roughly 60% of psychiatric in-patients and 50% of psychiatric out-patients, as compared with only 15% among "normal" sailor controls. Yet naval psychiatrists keep 9 out of 10 of the men referred to them as out-patients at duty and send back to duty 2 out of 3 of their in-patients. Moreover, the relapse rate as judged by readmission to hospital does not seem unduly high. Thus, according to an investigation made last year, psychiatric cases were being returned to duty from hospital at about 5 times the rate that relapsed cases were being readmitted, and about half of these relapsed cases had remained outside hospital for more than 6 months. Finally, of those that are invalided for psychiatric disorders, two-thirds have survived in the Navy for over a year.

The significant thing about these findings seems to be that although a high proportion of those who break down not only give a past history which suggests their predictability as bad psychiatric bets, but also show that they were bad bets by having broken down, yet it is still possible to send the majority of them back to duty and to retain a relapse rate that seems reasonably small. This is, of course, not to doubt the desirability of selection procedures. The standard adopted for rejection or early elimination must naturally depend upon the available man-power; but a number do remain who should be rejected, no matter what the man-power position may be. It seems doubtful, however, whether in the Navy the proportion that should certainly have been rejected or eliminated amounted at most to more than 1 to 2%. This may seem a small number, yet the trouble these men cause is out of all proportion to their actual numbers, when considered in terms of hospital treatment, inefficiency, letting down others, and impairing morale. A great stand-by in the Navy has undoubtedly been the self-selection consequent upon men expressing a naval preference at the time of their call-up, for reluctant dragons do not make the best fighting material.

It seems reasonable to conclude that many "bad psychiatric bets" give very fair service before they break down and are also capable of giving further fair service after they have done so. These facts should counteract any undue pessimism that may exist as to the capacity of the neurotic to stand up to the stress of war. There can be little doubt that an additional factor inducing unwarranted pessimism is the abnormal or at least different situation that occurs in shore establishments, and particularly in hospital, compared with life afloat. The picture seen in hospital is especially misleading, and makes a correct assessment extremely difficult.

Treatment

Apart from the real, though limited, place that exists for pre-selection, probably the most that would be desirable prophylactically would be a warning to survivors and others going on leave from sea that anxiety would be experienced temporarily and should not be misinterpreted as illness. The vast majority of men, however, deal with their experiences quite adequately without outside help, and certainly any prophylactic "pep talks" of the above kind should be given by executive officers and not by medical men.

Once a pathological tension state has become established it must be dealt with either by reducing the tension or by raising the tempo. The latter can be accomplished by an early draft to sea before habituation, including doubts about future capacity, has occurred. Failure may result if the ship lies in harbour for too long a period.

Reduction of tension can be produced by sedation, and the barbiturates are eminently suitable for this purpose. Tremulous agitated patients should be put to bed, and 48 hours' sedation will make discharge to hospital unnecessary in the overwhelming majority. The average case seen as an out-patient in a naval depot shows a steady decrement of tension at a rate which is extraordinarily consistent. The administration of phenobarbitone in three doses of half a grain daily for one week,

followed by the same dose twice daily for two weeks, usually brings about clinical recovery. With the other factors in treatment and management this paper is not primarily concerned. It may be worth noting that what medical men now effect with barbiturates humanity has accomplished for hundreds of years with the aid of alcohol. It is a sobering reflection that humanity was abreacting its pent-up emotions in parties with the aid of alcohol long before narco-analysis and group therapy were introduced for the same purpose.

"All theories are crutches, not sceptres or wizards' wands," and it is not suggested that the concept of post-operational strain that has been outlined is the whole story, but merely that it is perhaps a somewhat neglected part of it. Numerous other factors obviously help to make stress more tolerable and hence affect the incidence of neurosis, such as discipline, leave, mail, and the rapid solution of what are felt to be inequalities of treatment—to mention only a few. The Navy is, moreover, singularly fortunate in having a tangible object which is also a home around which group loyalty can centre—namely, the ship. An airman or member of the Tank Corps cannot feel about their contraptions in quite the same vividly personal way. Yet the life of a closed community, as in a ship, has its special dangers. Interesting browned-off (what the sailors call "chocker") paranoid reactions, rather similar to those seen among prisoners, may occur when the commission is too long or the ship is not a happy one. Dr. Johnson's dictum may be recalled: "No man will be a sailor who has contrivance enough to get himself into a jail; for being in a ship is being in a jail with the chance of being drowned." The rest of the quotation—"a man in jail has more room, better food and, commonly, better company"—is perhaps less acceptable.

There can also be little doubt that the group spirit and loyalty that exist on board ships are most potent factors in sustaining morale and that, conversely, the lack of this same group spirit and loyalty when a man leaves his ship and goes to a drafting depot is a most important factor in precipitating the breakdowns that occur there with so much greater frequency.

Summary

An endeavour has been made to show that psychiatric casualties attributable to operational stress occur most commonly after rather than during the stress.

Thus it has been pointed out that the psychiatric sickness rate is very much greater ashore than afloat.

The thesis is submitted that this is often due to a persistence of the physiological increase in tension developed at sea and rendered obtrusively uncomfortable by the suddenly reduced tempo on coming ashore; the reaction being analogous, in slow motion, to the normal experience of feeling worse after danger than during it.

While unworthy motives play an important part in perpetuating their role in producing the state can easily be over-estimated.

While pre-selection has a definite value, the practical importance of selection procedures is much modified by the fact that a substantial majority of psychiatric casualties can be returned to full duty.

Symptomatic relief often follows reduction of tension by sedation and increasing the "tempo" by early draft to sea before habituation has occurred.

SCHICK REACTIONS IN RECENTLY CONFINED WOMEN AND THEIR INFANTS

BY

G. PAYLING WRIGHT, D.M., F.R.C.P.

AND

W. M. CLARK

(From the Department of Pathology, Guy's Hospital Medical School)

It is now generally recognized that the resistance of newborn infants to diphtheria depends chiefly upon the passage of maternal antitoxin through the placenta during the last part of gestation. So readily can this antibody enter the circulation that at birth its concentrations in the serum of mother and infant are almost equal. From early childhood onwards any insufficiency in the concentration of circulating antitoxin to ensure immunity to clinical diphtheria may be readily demonstrated by a positive reaction in the Schick

doctor, there is little time for psychotherapy, and that therefore the untrained doctor is just as much a danger to the community as an untrained layman. Your correspondent draws a distinction between those who are skilled in psychotherapy and those who are unskilled, but fixes the dividing line between the sheep and the goats at the qualifying examination for medical degrees. Surely the only criterion in this matter is whether a psychotherapist has been trained in psychotherapy. The case for restricting the practice of psychotherapy to the medical profession alone is rapidly losing support, and the view is gaining ground that psychotherapy, like dentistry and massage, demands a special training on its own account, and that this training might quite properly be given independently of medical qualifications.

There are many highly skilled psychoanalysts whose results both clinically and in research are as satisfying as those of any medical psychologist. Among them are Mrs. Melanie Klein and Dr. Susan Isaacs, neither of whom holds medical qualifications, the supreme value of whose pioneer work, particularly in the psycho-analysis of children, is fully recognized by all medical men who are acquainted with it. All lay analysts who are recognized by the Institute of Psycho-Analysis are under covenant not to accept patients for treatment except from a medical man. In this respect they are exactly on a par with chartered physiotherapists and other registered medical auxiliaries. The sweeping condemnation of all lay psychotherapy should therefore be modified to exclude those responsible practitioners who, although unqualified in the medical sense, have devoted their life-work to the specialized knowledge necessary for this branch of healing.—I am, etc.,

Hayle, Cornwall.

D. STANLEY-JONES.

The Surgeon and the Anaesthetic.

SIR,—I have read with interest the letters of Drs. Ayre and Westell (Aug. 19, p. 254). One point seems to have been overlooked: if a patient dies on the operating table the only person held responsible by the coroner at an inquest is the anaesthetist. It is therefore the duty of all anaesthetists to place themselves in such a position that they can answer two questions: (1) Was the anaesthetic the right one for the patient and type of operation? (2) Was the anaesthetic administered with due skill? Thus all anaesthetists must judge each case on its merits, and not be provoked by the surgeon into giving an anaesthetic which makes the surgeon's task easier at the expense of the patient.

Skill can only come from experience, and too much should not be expected of a newly qualified man. I always answer a surgeon who asks me to push the patient deeper by asking if I can change places with him.—I am, etc.,

Birkenhead Municipal Hospital, Cheshire JOHN HERBERT HANNAN.

The D.P.M. Examination

SIR—The letter from my anonymous colleague "Major, R A M C. Senior Psychiatrist" (July 15, p. 102), raises a matter of much interest and importance.

The D.P.M. examination has certainly acquired an excessively neurological bias. The origin of this is a matter for speculation. Is it the reaction of the older school against the concept of the "disembodied mind" held by some analytical psychiatrists, or is it a guilt reaction on the part of those who have sought to cure cerebral tumours by psychotherapy? Possibly the explanation lies in the fact that there is no diploma in neurology.

The present form of the neurological examination appears to be designed to test the candidate's ability as a specialist in neurology. An understanding of the relationship between organic and psychogenic factors in such conditions as epilepsy and migraine, and an appreciation of the psychological manifestations of certain neurological disorders, are certainly of importance to the psychiatrist, but is neurology otherwise any more important than other branches of general medicine, of which a psychiatrist needs a full knowledge but which are entirely ignored by the D.P.M.?

Your correspondent's remarks on "psychiatry, psychology, or mental deficiency" and again "psychological medicine or mental deficiency" call for comment. Surely the study of mental

deficiency is an integral part of psychological medicine or psychiatry, and not a subject apart; Army psychiatry alone suffices to illustrate this point. "Mental deficiency" has too long been envisaged as a matter of clinical oddities such as epiloia and naevoid amentia by those with little experience in the subject, whereas its immense sociological importance lies rather in the recognition of behaviour disorders and social inadequacy due to constitutional causes or to disease or injury in childhood.

The ideal pattern for the final part of the D.P.M. examination would appear to be an extension of that proposed by the Royal Medico-Psychological Association immediately before the war. There should be a paper and viva covering all branches of psychiatry and those aspects of neurology, endocrinology, etc., which have a direct bearing on the subject: then there should be a further paper and viva designed to test the candidate's more intimate knowledge of the particular branch in which he has had special experience. The examiner in the special part of the examination should be a psychiatrist experienced in that particular branch. Subjects such as psychosis, psychoneurosis, mental deficiency, delinquency, and child guidance could each be dealt with in this manner.—I am, etc.,

Aberystwyth.

C. GUY MILLMAN,
Major, R A M C.

Ministry of Health's Social Survey

SIR,—In an answer by the Minister of Health to a question put simultaneously by General Clifton Brown and by myself (*Hansard*, Aug. 3, col. 1643) and reproduced in your issue of Aug. 19 (p. 257), the Minister justifies the procedure criticized by us on the ground that "the survey is providing information which is essential to a proper understanding of health statistics, and which cannot be attained in any other way."

The procedure is described in greater detail in the monthly bulletins of the Ministry of Health for April, May, and June, 1944. It would seem that under this procedure lay visitors descend upon selected members of the public and submit a questionnaire designed to ascertain the incidence of illness and injuries. The questionnaire includes inquiries as to the character of the past illnesses—usually self-diagnosed—of the persons visited, and further inquiries as to the number of visits made, either at their homes or to doctors' houses, by the family practitioner in charge of the patient. No reference would seem to have been made to the doctors concerned in checking either the diagnoses or number of visits alleged to have been made.

In certain well-attested instances the visitor, zealous to acquire merit with the Ministry, has insinuated that the patient would receive much better attention under the proposals for the future medical service outlined in the White Paper. The value to "a proper understanding of health statistics" of data so compiled would seem questionable. The report of the survey is contributed by the medical statistician to the Ministry of Health, a salaried Civil Servant whose experience of medical practice would seem to have been negligible, but no other check of the returns thus made would appear to have been carried out.

This method of survey seems to have been initiated by the Ministry of Information when Mr. Duff Cooper was the Minister, and the description of the persons thus employed as "Cooper's snoopers" contributed materially to the demerit of that effort under the storm of ridicule which followed in Parliament and in the Press.—I am, etc.,

House of Commons.

E. GRAHAM-LITTLE.

The G.P. and Service Medicine

SIR,—In spite of the lapse of time I feel that a few words on the above subject by a former G.P. would not be amiss. It is a peculiar fact that so far all the letters, with the exception of one from a civilian colleague, have been from specialists. Now specialists in the medical services, though not given such a great degree of variety, do have the opportunity to practise their speciality to a greater or less degree. But in what branch can the G.P. take his place? The usual answer is as an R.M.O. Granted, the "joy and spirit of comradeship," as Major Kean says, will be there, unless the M.O. is an obvie-

The Services

CASUALTIES IN THE MEDICAL SERVICES

Squad. Ldr. ROBERT GORDON SHARP GRANT, who was killed on June 6 on the Normandy beaches, aged 32, studied medicine at Edinburgh University and graduated M.B., Ch.B. in 1938. After holding house appointments at the Royal Infirmary, Edinburgh, and Seafeld Maternity Hospital, he was appointed to a commission in the medical branch of the Royal Air Force Volunteer Reserve on June 25, 1940.

Died of wounds.—Major R. R. Maitland, R.A.M.C., Lieut. W. H. Black, R.A.M.C.

Wounded.—Temp. Lieut.-Col. W. J. Young, I.M.S.; War Subs. Capt. M. S. Howe, W. R. C. Lang, and R. J. Waugh, and Temp. Major E. R. Smith, R.A.M.C.

Missing.—Capt. R. A. B. Kinloch, R.A.M.C.

DEATHS IN THE SERVICES

Surg. Rear-Adml. GUY LESLIE BUCKERIDGE, C.B., O.B.E., who died in London on July 14, was born in 1877 and qualified M.R.C.S., L.R.C.P. from Guy's Hospital in 1903, and then joined the Navy as a surgeon. He served at Osborne and at sea in the last war, afterwards became Deputy Director-General of the Medical Department at the Admiralty, and was later in charge of the Royal Naval Hospital, Haslar, retiring in 1937. During the later years of his service he was Honorary Surgeon to the King. Admiral Buckeridge had joined the B.M.A. in 1920, and while at Haslar was elected an associate member of the Portsmouth Division. Dr. G. de Swiet sends the following tribute: The passing of Surgeon Rear-Adml. G. L. Buckeridge has robbed the Willesden No. 1 National Service Medical Board of its beloved chairman. It was a privilege to be ruled by such genuine kindness and amiability during these five weary years of stress and sorrow. The great responsibility of one's task was often lightened by "the Admiral's" perfect tact, unfailing good humour (in spite of indifferent health), and his broad-mindedness. He was an exceptionally well-read man, and for a medical man he possessed an unparalleled knowledge of European literature of the classical type, especially Russian and French. He was equally well versed in philosophy and history, and a brief chat with him on any of these and any other subject—between the "cases"—went a long way towards relieving the inevitable pressure and monotony of work. When occasion occurred he was ready to wield a subtle and satirical pen, raised against harshness or incompetence. He was incapable of arousing enmity, for he was disarmingly quick in admitting an error and making amends. His frail physique and gentle yet worldly manner gave one infinitely more the impression of a courtier than of a sailor. Both doctors and clerks have the sense of a deep and irreplaceable loss.

Medical Notes in Parliament

Cancer: Service Pensions

In the House of Commons on July 25 Mr. LIPSON drew attention to the refusal of the Minister of Pensions to grant pensions to two men who had been discharged from the Services suffering from cancer. Sir WALTER WOMERSLEY, replying, said he must take the consensus of medical opinion in arriving at a decision whether a certain disease was due to or had been aggravated by service. It was inevitable that cancer might, from time to time, show itself during service, and his Department had to consider whether or not service had played any part in its onset or development. Although the actual cause of cancer was not known, there had for a long time been a general medical agreement on certain conditions which might possibly be related to its onset and also on other conditions which were certainly not so related. The Medical Research Council, at the request of his Department, convened a conference of experts, which gave comprehensive advice on the conditions affecting different forms of cancer and the sites in which they occurred, and this advice could be taken as constituting a consensus of medical opinion. It was, in general, to the effect that it was only in exceptional cases that the development of cancer might possibly be attributed to, or influenced by, a previous injury or disease arising out of war service, and certain criteria were laid down as affording a basis for decision. Each case of cancer was considered by his Department in the light of this advice, and, although it had not been possible to accept the vast majority of cases, yet, in an appreciable number, where a reasonable doubt could be said to exist, entitlement had been conceded. So it was not true to say that the Ministry had not granted pensions even for cancer if circumstances warranted it.

Colonel CLARKE asked if failure on the part of a medical officer to diagnose cancer, with the result that the man was treated wrongly and lost his life, was not considered an aggravating cause. He said he had heard of cases where men had been wrongly diagnosed, had been treated for something else, and had died. Sir WALTER WOMERSLEY: If it were a case of wrong diagnosis and that was shown to me clearly as the reason for a man's life being shortened, it would be a case for pension.

Finance of the White Paper

Replying in the House of Lords on July 20 to a debate on the cost of social reform, Lord WOOLTON said that to maintain a higher standard of health the country would have to find for the early years of the National Health Service, £148,000,000 a year from rates, taxes, and contributions from the Insurance Fund. Before the war the cost to public funds was £61,000,000. Of the increase, some £40,000,000 must be reckoned as transferred from one type of payment to another. Some of the remaining difference must be attributed to the rise in price. At current rates of absence from work through sickness the loss might amount to £280,000,000 per annum. Present rates of absenteeism were high as a result of long hours, the number of married women in industry, and the withdrawal of the younger men to the Forces. The loss which might be expected in a year after the war was £180,000,000 unless the standard of health could be improved. The expenditure proposed in the White Paper on the Health Services would, he believed, prove a profitable expense.

Inquiry into Veterinary Practice.—Mr. Robert Hudson and Mr. Tom Johnston have appointed a committee to inquire into the extent and effect of veterinary practice in Great Britain by persons who are not registered veterinary surgeons and to make recommendations as to any measures which may be desirable to limit or regulate such practice. Its members are: Sir John Chancellor (chairman), Mr. A. C. Brown, Sir Daniel Cabot, Mr. J. W. Salter-Chalker, Mr. Charles Dukes, Prof. James Gray, Mr. C. M. Holmes, Mr. W. F. Holmes, Mr. Robert Hobbs, Mr. W. D. Jackson, Sir Louis Kershaw, and Lieut.-Col. P. J. Simpson.

Penicillin: Large-scale Manufacture.—On July 25 Mr. SALT asked the Minister of Supply whether, in view of the desirability of removing all obstacles to the rapid development of the large-scale manufacture of penicillin, he would now agree to permit full publicity with regard to the methods of manufacture and withdraw those objections hitherto raised on security grounds. Mr. CHARLES PEAT, who replied, said he was not aware that large-scale production of penicillin was being impeded through lack of information. The general method of manufacture had been published in the technical press.

Blind Persons in Industry.—On July 25 Mr. THORNE asked the Minister of Health the number of blind persons in the United Kingdom, how many were fully employed, and what reports he received on the degree of satisfaction given by them at the places of employment. Miss HORSBROUGH said that on March 31, 1943, the number of employment figures were available, the number of registered blind persons in the United Kingdom was about 90,000. About 10,000 were employed or working on their own account, but some of these (perhaps 1,000) were part-time workers only. She was informed by the Minister of Labour that the reports on blind persons engaged in ordinary industry were very satisfactory.

Intelligence Tests for Army.—On July 25 Sir JOHN GRAHAM KERR asked the Secretary of State for War whether, in view of the increased recognition of the importance of a high standard of powers of observation and of general mental alertness, he would institute adequate examination tests in these for all candidates for commissions in the Army. Sir JAMES GRIGG said that all recruits on entering the Army and all candidates for commissions were given intelligence tests which measured their mental alertness. Candidates for commissions who passed through War Office Selection Boards—this covered all but a small number who were commissioned directly into technical arms—were given practical tests which measured their powers of observation and their mental alertness. The importance of these qualities was fully appreciated.

Output and Working Hours.—Mr. ROSTRON DUCKWORTH on July 27 asked Mr. Attlee whether, as the report of the Industrial Health Research Board could not state whether reduced working hours increased or decreased output, he would arrange for the Medical Research Council to continue its investigations along the same lines. Mr. ATTLEE said the Industrial Health Research Board of the Medical Research Council proposed to investigate this subject further as opportunity permitted. It had been firmly established that, except for brief periods of special emergency, working hours in manual operations should not exceed 60 to 65 for men and 55 to 60 for women. The point not yet decided conclusively was whether reduction of working hours below those limits had a further beneficial effect measurable in terms of output. The report indicated the practical difficulties in reaching a clear decision on this question by investigations carried out under the unstable conditions of wartime.

Notes in Brief

The committee appointed by the Medical Research Council to investigate jaundice has collected much information, but the causes of the disease are still not fully known. Research is being continued.

misfit, but as soon as the relief from overwork in wartime general practice is over, and indulgence in extra alcohol and short hours have served their turn, the G.P. wants to get back to the work for which he has been trained. Regimental work does not give him this; the excitement of action is probably less than 5% of his service, the remaining 95% is boredom—the usual percentage of any war. An R.M.O.'s duties, besides inoculations, inspections, and advising the C.O. on a few aspects, consists of "knowing his men" and seeing them on sick parade, when any sick must immediately be sent to hospital as the equipment provided lacks the essentials for diagnosis—auriscope, microscope, sphygmomanometer, etc. To get to know his men well is difficult because he holds a commission, and to increase further the mistrust is his "friendliness" with the C.O. In addition, the wife, family, and home surroundings are unknown except through censorship.

In the absence of enemy action G.P.s suffer from intense boredom after about a year unless their interest in medicine has lapsed. Being a C.D.O. in a base hospital is often little better than being a third-year dresser in the medical or surgical wards and little responsibility is given him, the M.O., unless a "specialist," being incapable of making a diagnosis or prescribing treatment without supervision. It is better, I believe, to be in an advanced hospital centre. Another alternative is to become a soldier in a collecting unit, and see even less medicine in a job which could often be carried out satisfactorily by an infantry officer with first-aid training. A further alternative is to become an administrative officer—second in command of a hospital, etc.—and see no medicine at all, unless the specialists are interfered with. Finally, the only way a G.P. can hope to do any medicine is to become a graded specialist, often in a subject in which he is not keenly interested but which is the least of the "evils."

These few remarks, in my opinion, more truly represent the G.P.'s view than those previously published. The inevitable result of either an Army or a State service is the abolition of the "family doctor," and in his place a sergeant of the R.A.M.C. referring the majority of cases to dozens of specialists of lower qualifications than is the case at present.—I am, etc.,

D. S. PIPER,
Capt., I.M.S., I.A.M.C.

Bombay.

Seeing is Believing: Medical Films

SIR.—The annotation on seeing is believing (Aug. 26, p. 281) invites a reply. The Medical Standing Committee of the Scientific Film Association is ready to answer the query: "Who is to sponsor such films, and with what immediate and remote objects?" This standing committee is ready for the following immediate duties: (1) to "sponsor" medical films of approved quality, both medical and photographic; (2) to "appraise" medical films, and especially those for instructional use; (3) to provide, in fact is in the process of forming, a "nuclear" library of medical films; (4) to receive answered questionnaires with details of such films, so that all selected can be catalogued in a central medical film library as soon as possible after the cessation of hostilities; (5) to help with suggestions as to the making of medical films; (6) to arrange for the exhibition of such films.

We greatly hope that every medical practitioner who has made a medical film will write at once to Dr. Seymour Reynolds, 14, Hopton Road, Streatham, S.W.16, for a copy of the medical film questionnaire. The matter is really urgent, and we ask for prompt co-operation.—We are, etc.,

W. MCADAM ECCLES,
Chairman.

S. J. REYNOLDS,
Hon. Secretary.

Medical Standing Committee of the Scientific Film Association.

P. G. Boman (*Ann. intern. Med.* 1944, 20, 779), who records seven cases of primary carcinoma of the jejunum and ileum, states that this condition is relatively rare and difficult to diagnose. Adenocarcinoma of the annular constricting type is the commonest variety. Few cases are diagnosed before obstruction symptoms have appeared and metastases are present. Careful evaluation of early symptoms, a thorough x-ray examination of the small intestine and exploratory operation are needed to improve on present results.

Obituary

G. W. FITZ-GERALD, M.D., F.R.C.O.G.

Dr. Gordon William Fitz-Gerald, O.B.E., T.D., who died on Aug. 18 at West Didsbury, Manchester, aged 72, studied medicine in Edinburgh, Paris, and Dublin, graduating M.B., C.M.Ed. in 1898, taking the L.M. of the Rotunda Hospital in 1899, and proceeding M.D. in 1901. After holding the post of senior assistant master at the Rotunda he began gynaecological practice in Manchester, and was elected to the honorary surgical staff of the Clinical Hospital for Women and Children—now the Northern Hospital; later he was appointed to the specialist staff of the Manchester Municipal Hospital, and lecturer to the nurses there.

Dr. Fitz-Gerald became well known as a consultant and writer on his special subject, taking part in the local scientific meetings, and was for a time president of the North of England Obstetrical and Gynaecological Society. He also acted as examiner for the medical degrees of Durham University and for the School of Medicine in Cairo. He was one of the first to be elected F.R.C.O.G. in 1929, in which year he held office as vice-president of the Section of Obstetrics and Gynaecology at the Annual Meeting of the B.M.A. in Manchester. For many years he was a prominent member of the Northern Counties Lawn Tennis Club and of the Didsbury Golf Club, becoming president of each. He was also one of the best-known croquet players in the district, and will be remembered by many onlookers for his skill in this most deliberate of all outdoor games. In 1917-19 he was in command of the Fusehill Hospital, Carlisle, with the rank of Lieut.-colonel, R.A.M.C.(T.), and during the present war he was for a time in charge of the Didsbury Military Hospital. His chief contributions to medical literature were on post-partum haemorrhage and malignant disease of the vagina and cervix.

H. ALEXANDER FRANCIS, M.B.

Dr. Alexander Francis of Wimpole Street, who for many years practised as an asthma specialist in London, died at West Hothly on Aug. 13. He was born at Brisbane on Aug. 11, 1863, the third son of Arthur Morley Francis, a police magistrate and member of the Legislative Assembly of Queensland.

He was educated at Brisbane Grammar School and entered St. John's College, Cambridge, in 1883. At Cambridge he was captain of the Lady Margaret Boat Club, won the Pearson and Wright Sculls, and rowed in the university trial eights. He entered St. Bartholomew's Hospital in 1886, where he worked under Sir William Savory, Howard Marsh, and Dr. James Andrew. In his autobiography *Then and Now* (Chapman and Hall, 1935) he gives a most interesting account of Savory and his opposition to Lister. It was, however, working as clinical assistant to his cousin, Dr. Greville McDonald, at the Throat Hospital, Golden Square, that he first became interested in what was to be his life-work. He took the M.B., B.Ch.(Cantab.) in 1890, intending to return to Queensland. But before doing so he was told that the Cambridge degree was practically unknown in the Colonies, and if he did not take the M.R.C.S., L.R.C.P. people would think he was not properly qualified. So he also took the Conjoint diplomas in 1890. For two years he was in charge of bush hospitals in the back blocks of Queensland, where he was the only surgeon, physician, and obstetrician for an area of 100 square miles. It was an experience which he always said was of inestimable value to him in later life. Then he started in Brisbane as an ear, nose, and throat surgeon, at that time an almost unknown specialty. It was here that he first became interested in asthma, and in his autobiography he gives a vivid account of how the treatment, later associated with his name, originated.

On a visit to England in 1902 he read a paper at the Clinical Society on the treatment of asthma which caused much interest and not a little hostile criticism. His results, however, were so impressive that he was encouraged to return to practice in this country: he did so, and for the next 40 years practised in the Harley Street area, expounding his views on the aetiology, symptoms, and treatment of asthma at meetings of the British Medical Association, in the medical journals, and in two books *Asthma in Relation to the Nose* (1903) and *Asthma and its Treatment* (1932). He held the view that asthma is a disturbance due to instability of the vasomotor system, and that symptoms are caused by swelling of the bronchial mucosa, thus narrowing the lumen, and not by spasm of the bronchial musculature—the usual explanation. The rapid

MEPACRINE FOR MALARIA

We print below a statement on the present position of mepacrine in the treatment of malaria which has been issued by the Medical Research Council Committee on Malaria.

In view of the great importance of malaria for warfare in the Far East and also in the Mediterranean region, a great deal of work has been carried out during recent years to evaluate the relative merits of the two chief antimalarial drugs available at the present time—namely, mepacrine (atebrin, quinacrine) and quinine. The conclusions reached are shown by the resolutions (reproduced below) which have recently been adopted by the appropriate official bodies in the United States and in this country.

According to the *Journal of the American Medical Association* (1944, 125, 977) the Board for the Coordination of Malarial Studies adopted the following resolution concerning the relative value to the armed Forces of mepacrine (quinacrine hydrochloride U.S.P.), quinine, and totaquine (U.S.P.).

"On the basis of controlled quantitative studies in civilian, Army, and Navy establishments, the evidence at hand justifies the following statement:

1. *In the Suppressive Therapy.*—Mepacrine (atabrine) has proved to have all the antimalarial properties ascribed to quinine in the suppression of malaria during and subsequent to exposure to infected mosquitoes. Effective suppression can be accomplished over long periods of time by proper use of mepacrine. Available evidence indicates that this end may be achieved without danger to the individual. Earlier reports indicated a significant incidence of gastro-intestinal disturbances in certain groups of men receiving suppressive mepacrine therapy. For practical purposes these adverse reactions can be avoided by proper administration of the drug. Quinine, in doses adequate to assure suppression of malaria equivalent to that produced by mepacrine in the dosage currently used by the armed Forces, is frequently attended by symptoms of cinchonism. Mepacrine has been demonstrated to prevent consistently the development of falciparum malaria when the drug is administered in proper dosage before, during, and after exposure.

2. *In the Therapy of the Acute Attack.*—Experience in the past two years has demonstrated conclusively that mepacrine (atabrine) when properly administered is fully as effective as quinine in the termination of the acute attack and is safer than quinine. The intramuscular injection of mepacrine is highly effective in securing a rapid therapeutic response. Evidence is not at hand to decide on the relative merits of mepacrine administered intramuscularly as compared with quinine administered intravenously in patients with fulminating cerebral malaria.

3. *In the Therapy of Vivax Malaria.*—Neither mepacrine nor quinine can be relied on to prevent relapses in vivax malaria following the discontinuation of therapy, although the interval between attacks is significantly longer following mepacrine than following quinine in the dosage schedules currently used by the armed Forces.

4. *In the Therapy of Falciparum Malaria.*—There is convincing evidence that mepacrine not only suppresses the clinical symptoms of falciparum malaria but also cures this malignant form. The evidence of a similar curative effect of quinine is not conclusive.

5. *Totaquine (U.S.P.).*—Because of its content of crystallizable cinchona alkaloids, totaquine (U.S.P.) has activity which approximates that of quinine and therefore can be used as a substitute for quinine when given orally. The antimalarial activity of totaquine (U.S.P.) is dependent on the amount of crystallizable alkaloids in the preparation rather than on the specific amount of each individual alkaloid. Gastro-intestinal disturbances occur more frequently following the use of the present totaquine (U.S.P.) than they do following the use of quinine or mepacrine.

On the basis of the foregoing statement it is resolved:

1. That no advantage, and possible disadvantage, would accrue to the armed Forces were quinine or totaquine to replace mepacrine for the routine suppression and treatment of malaria.

2. That the large-scale production of quinine or totaquine is not now considered a matter of importance for the management of malaria among Army and Navy personnel. It is possible that a supply of totaquine in excess of the present stockpiles may be required for therapy in civilian populations temporarily under the jurisdiction of the armed Forces in occupied territory where immediate dissemination of informa-

tion concerning the use of mepacrine (atabrine) is not practicable. In this connexion it should be kept in mind that after the war the overall need for all established antimalarial drugs will continue to be great."

The personnel of the Board is: R. F. Loeb (chairman), W. M. Clark, R. G. Coatney, L. T. Coggeshall, F. R. Dieulaide, A. R. Dochez, E. G. Hakansson, E. K. Marshall jun., O. R. McCoy, F. T. Norris, W. H. Sebrell, J. A. Shannon, and G. A. Carden jun. (secretary).

This resolution was considered by the Drug Prophylaxis and Therapy Subcommittees of the Medical Research Council Committee on Malaria at a joint meeting on Aug. 23, 1944. (The personnel of these subcommittees is: Major-Gen. A. G. Biggam (chairman), Brig. F. A. E. Crew, Col. S. P. James, Dr. W. D. Nicol, Lieut.-Col. B. Maegraith, Col. C. S. Ryles, Mr. P. G. Shute, Brig. J. A. Sinton, Air Marshal Sir H. E. Whittingham, Dr. F. Hawking (secretary). The various items were discussed, and it was agreed that British experience, and the extensive investigations carried out in Australia under the direction of Brig. N. Hamilton Fairley, led to the same conclusions as those which had been reached in America. In particular, the subcommittee endorsed the resolution that if quinine or totaquine replaced mepacrine for the routine suppression and treatment of malaria the change would not be advantageous and might possibly be disadvantageous.

It is not possible during wartime to disclose all the extensive investigations upon which these official American and British resolutions concerning the relative merits of mepacrine and quinine have been based, but when peace returns full details will doubtless be published in the scientific press. Meanwhile the position may be summed up by saying: Under proper administration mepacrine is no more liable to cause serious toxic effects than quinine is; mepacrine is as effective as quinine in the therapy of vivax malaria, but neither compound will prevent relapses at a later date; mepacrine if properly given will practically always suppress and cure falciparum malaria, while the action of quinine in this respect is less certain.

Accordingly it must be realized that mepacrine is not an inferior substitute for quinine forced upon us by the loss of Java, but it is a more effective agent against malaria which would still be employed even if the supplies of quinine were unlimited.

MEDICAL RESEARCH IN SOUTH AFRICA

The annual report for 1943 of the South African Institute for Medical Research, Johannesburg, tells of further expansion of the South African Medical Corps Laboratory Service. This organization now includes seven large and fifteen small laboratories, in addition to the two mobile units based on the institute for field duties. An innovation has been the posting of junior naval medical officers from H.M. hospital ships for short courses at the institute in tropical medical and allied subjects. Among the field units the snake-catchers' section, operating in the Komatipoort area, caught from 50 to 75 cobras and puff adders every month to provide venom for the production of antivenene. The newly formed section of gerbil catchers, working in the Benoni-Middelburg area, caught approximately one thousand gerbils a month for the typhus vaccine department. By the end of the year the monthly production of vaccine was nearly 40,000 doses. Experiments in the prophylaxis of typhoid fever by the intradermal injection of typhoid vaccine proved satisfactory; this method uses less vaccine, and there is neither local nor general reaction.

Vitamin assays revealed that processed cheese is an excellent vehicle for fish-liver oils. The survey of vitamins in African food-stuffs, continued during the year, included the completion of the study of the thiamine content of maize, Kaffir-corn, and other cereals. It was found that the thiamine content of millet is extremely low. Among legumes, the beans to which the native population is especially addicted, notably the speckled sugar-bean and the njugo bean, were found to have the lowest thiamine content.

Mrityunjoy Mitra, ship doctor, has been appointed M.B.E. (Civil Division). The citation in the *London Gazette* reads:

When the ship was sunk by a raider, Dr. Mitra was taken prisoner and, after being kept on the prison ship for two and a half months, was interned in prisoners of war camps in France and Germany. While he was on board the prison ship, Dr. Mitra acted as doctor for the 343 prisoners. During his detention in Germany he attended Merchant Navy personnel and in addition had 1,100 other prisoners under his care, mostly Orientals. Dr. Mitra showed exceptional devotion in undertaking this work voluntarily. There is little doubt that he did much to alleviate the sufferings of his fellow prisoners and to maintain general health in the camp, although his own health was so bad that it eventually resulted in his repatriation.

effect of adrenaline in reducing swelling seems to support this view of his, as does also its success in the associated condition of giant urticaria and angioneurotic oedema. His theory was that, by stabilizing the vasomotor mechanism, asthma in a large percentage of cases, particularly if the blood pressure was high, could be completely stopped; and that, moreover, when the vasomotor system had been stabilized the usual irritants no longer produced an attack. His method of treatment was to cauterize *lightly* certain asthmogenic spots on the mucous membrane of the nasal septum. By this means he obtained striking results over many years, and earned the gratitude of innumerable patients. He particularly emphasized the fact that the cauterization must be extremely light—a point overlooked by many who attempted to carry out his treatment.

Like his father, he was a pioneer. He was interested in every new advance in medical science, and kept in touch with modern thought. He was one of the oldest members of the B.M.A., one of the earliest presidents of the Queensland Branch, which he helped to found, and he was on the Central Ethical Committee for many years in London and on three occasions a member of Council. In his life he was almost selfless. He literally spent it in helping others. On his 81st birthday, two days before he died, he was still seeing patients. He was twice married, and is survived by two daughters and a son who is also an ear, nose, and throat surgeon.

J. J. A.

W. KNOWSLEY SIBLEY, M.D.

We regret to announce the death of Dr. W. K. Sibley, consulting physician to the St. John's Hospital for Diseases of the Skin.

Walter Knowsley Sibley, the eldest son of the late Mr. S. W. Sibley, F.R.C.S., was born in 1862. He was educated at University College School and Pembroke College, Cambridge, where he took a degree in natural sciences. He received his medical training at the Middlesex Hospital, qualifying in 1886. He took the M.D.Camb. and the M.R.C.P. in 1891. He was house-surgeon at the Middlesex, and house-physician at the Brompton Hospital. At one time Sibley was lecturer to the London School of Dermatology and physician to the North-West London Hospital. He held office in many medical societies, being at one time chairman of the Westminster Division of the Metropolitan Counties Branch of the B.M.A. Among his publications were *The Treatment of Diseases of the Skin*, and articles in various medical journals on the same subject. "He was," a colleague writes, "a friendly, popular, and congenial colleague, a vivid and energetic personality; and to the end was keenly interested in all that appertained to his special subject. A keen tennis player, he played regularly at his club until well past his seventieth year."

We regret to announce the death on August 18 at Douglas, Isle of Man, of Dr. CHARLES SATCHELL PANTIN, O.B.E., consulting surgeon to Noble's Isle of Man Hospital and surgeon to the Governor's Household. Dr. Pantin studied medicine at Guy's Hospital, graduated M.B., B.S.Lond. in 1892, and took the M.D. and F.R.C.S. in 1894, after serving as house-surgeon at Guy's and house-physician and house-surgeon at the Victoria Hospital for Children, Chelsea. In September, 1896, he was appointed the first assistant honorary surgeon to Noble's Hospital under a new rule of the committee, and in 1906 he became full surgeon. During his long period of service on the visiting staff of the hospital Dr. Pantin established himself firmly in the affections and goodwill of his colleagues and the community, and no medical man in the island stood higher in the esteem of Manx people. He joined the B.M.A. in 1906, was elected president of the Isle of Man Branch of the Association last year, and had been acting honorary secretary of the Isle of Man Medical Society. During the last war he worked as surgeon to the Fargo Military Hospital. In 1936 his public services were rewarded by appointment as an Officer of the Order of the British Empire. Two of his five children entered the medical profession—Dr. Dorothy Pantin and Dr. Charles Guy Pantin.

The following well known medical men have died abroad: Dr. ARCHIBALD JOHNSTON BUIST, emeritus professor of gynaecology at the Medical College of Charleston, aged 71; Prof. CARL HEGLER, director of the St. George's General Hospital and extraordinary professor of internal medicine at Hamburg, aged 66; and Geh. San. Rat. Prof. HERMANN WEBER, formerly director of the Medical Department of the Lazarus Hospital, Berlin, aged 78; Dr. ERNST EDENS, the eminent cardiologist and professor of internal medicine at Dusseldorf, aged 68; Prof. FRANZ LINKE, director of the Institute for Meteorology and Geophysics at Frankfurt University, one of the leading German bioclimatologists; Dr. ENRIQUE A. BOERD, professor of obstetrics at the University of Buenos Aires; and Dr. MAXIMO M. CASTEIGTS and Dr. ARRURO MO, of Buenos Aires.

The Services

Squad. Ldr. Ernest Reginald Brown, R.A.F.V.R., has been appointed O.B.E. (Military Division), and Corporal George Greenwood, R.A.F.V.R., has been awarded the B.E.M. (Military Division). The citation in the *London Gazette* reads as follows:

"In February, 1944, a Mosquito aircraft crashed and caught fire when approaching to land. The pilot was killed instantly, but the observer was alive, and rescue parties tried in turn to extricate him from the blazing wreckage. Party after party failed, and each attempt became more difficult owing to the increasing heat of the fire in the cockpit area of the wreckage. Eventually Squad. Ldr. Brown, the station medical officer, and Corporal Greenwood made a final and desperate effort as the situation had become critical because the supplies of foam were exhausted temporarily and the fire remained unchecked for some minutes. If their effort failed it was clear that immediate amputation of the observer's leg was the only way by which he could be released. Displaying extreme courage, Squad. Ldr. Brown and Corporal Greenwood withstood the intense heat of the flames and, by the skilful use of the tools at their disposal, succeeded in breaking away the wreckage which was trapping the observer's leg. They then removed the airman to the ambulance. While first aid was being rendered, Squad Ldr. Brown returned to the wreckage to make certain that the pilot was not alive. This officer and airman displayed outstanding courage and determination."

CASUALTIES IN THE MEDICAL SERVICES

Squad. Ldr. JOHN HENRY PERCIVAL GAUVAIN, M.B., B.Ch., was killed on Aug. 14 in a flying accident. He was born in August, 1915, studied medicine at Cambridge and St. Bartholomew's, qualified in 1939, and was appointed to a commission in the Medical Branch of the R.A.F.V.R. on Sept. 27, 1939. At the date of his death he was serving over-seas.

Reported missing—Surg. Lieut. C. J. S. Green, R.N.V.R.

DEATHS IN THE SERVICES

Major-Gen. GODFREY TATE, C.I.E., I.M.S., died on July 29 after a varied and distinguished career at the age of 71. He was educated in Belfast and at Trinity College, Dublin, where he graduated in medicine in 1896. In 1898 he took a good place in the entrance examination for the I.M.S., and during his early military service he was medical officer to an Indian cavalry regiment. He saw active service in China in 1900 and on the N.W. Frontier in 1903, with medals for each campaign. In 1913-16 he held the important post of surgeon to the Commander-in-Chief, India, and was civil surgeon in Simla during the next five years. In 1920 he was appointed professor of midwifery and gynaecology at the Lahore Medical College, where he found scope for his surgical abilities. On reaching the administrative grade he was successively Chief Medical Officer, N.W. Frontier Province, Acting Inspector-General of Civil Hospitals, Punjab, and Surgeon-General with the Government of Bengal, when he was promoted to the rank of major-gen. and was awarded the C.I.E. In these posts he proved to be an able and popular administrator, and in 1926 he was appointed to be an Honorary Surgeon to the Viceroy. His high qualities led to his being appointed in 1931 to be Governor and Medical Superintendent, King Edward VII Convalescent Home, Osborne, the first such appointment of a medical service officer other than those of the R.A.M.C., and he held the post with distinction for five years. He was also devoted to hunting, shooting, and golf. He will be missed by his many friends; his wife survives to mourn his loss.

Universities and Colleges

MCGILL UNIVERSITY, MONTREAL

A diploma course in tropical medicine is offered for the first time during the session 1944-5. Its object is to train medical graduates to deal with medical problems which may be met in tropical areas. The course is divided into several units, each consisting of approximately three months' work. Three units are required to qualify for the diploma. In this way the course will meet the needs of individuals with different previous training. A unit of three months in parasitology and tropical medicine is compulsory for all. Students who have recently graduated will be offered training in the out-patient departments of the hospitals associated with the University, and in the child welfare clinics. They will also have an opportunity to receive three months of practical experience in an approved hospital in the Tropics. This training will satisfy the requirements of a fifth year of professional training for students who wish to take the examinations of the Dominion Council. The course is also suggested as a refresher course for medical graduates who have been

months the amount hoped for in August had been maintained. He took responsibility for the arrangements made. The allocation was on a regional basis.

The decision on how that allocation should be used. Mr. Willink continued, was made by the university medical schools. Each school had set up its expert committee. Treatment was given in teaching hospitals and in other hospitals which had been approved for that purpose. Penicillin was not a drug which could be used with advantage in every type of disease. In some it might be the only means of saving life; in others an alternative to sulphonamides; in others it might be ineffective. Some doctors even asked for penicillin for use in cancer, mycosis fungoides, and chronic leukaemia, in which it was quite ineffective. It was only suitable in cases which were treated in a hospital or nursing home under continuous medical supervision. In an address last month Prof. Henry Cohen had said that doctors should deprecate public clamour by responsible and influential persons for the use of penicillin in an isolated case where large amounts might be necessary in treatment and where results were extremely doubtful, at the expense, perhaps, of several cases in which the use of penicillin would almost certainly turn the balance in the patient's favour. Advice issued by the Ministry of Health, based on that of a committee of experts from many fields, was contained in a memorandum on the conditions in which penicillin should be used and in others for which it should not be used. Recommended as *prima facie* suitable for treatment by penicillin were staphylococcal infections. These included septicaemia, early acute osteomyelitis, severe carbuncle, cavernous sinus thrombosis, or any other life-endangering infection. The second class for which use was recommended were haemolytic streptococcal, pneumococcal, and meningococcal infections and any life-endangering infection of the type which had failed to respond to adequate sulphonamide treatment. The third class was gas gangrene. It was, however, recommended that penicillin should not be used for rheumatic fever, ulcerative colitis or other intestinal infections, bacterial endocarditis, or syphilis. Reports from the hospitals indicated that supplies had proved sufficient for all suitable cases in the first group. There was no satisfying evidence at present on the effect of penicillin in the treatment of bacterial endocarditis. Some believed that if a patient seriously ill with this disease was given large doses he would show an immediate improvement, but that the condition would probably lapse and that more penicillin must be given. There was not yet evidence to show whether by continued treatment the patient could be definitely cured or kept alive. Mr. Willink announced that it was proposed to investigate the effects of penicillin on this disease and to see whether a method of application could be devised which was likely to be successful. The quantities allotted to his Department were being progressively increased. By January there would be twice as much available for civilian use as there was to-day. It would be wrong to use penicillin for our civilian population on a more lavish basis than the United States used it for theirs. Before the end of 1945 the penicillin available would meet all, or nearly all reasonable demands.

Planning for Social Security

Sir WILLIAM JOWITT on Nov. 2 asked the House to approve the intention of the Government, as declared in the recent White Paper, to establish an enlarged and unified scheme of social insurance and a system of family allowances. He said the Government had addressed itself in an effective manner to an intricate job. In the main the proposals were not new. Social insurance had long been an essential feature of the national life. The time had come for improvement of existing benefits and for the introduction of new ones on the lines of bringing everyone into the new scheme and of welding fragments into a comprehensive whole. The benefits were calculated actuarially, and the taxpayer would pay one-sixth of the various benefits, except for unemployment insurance, where he pays to-day and is to pay in future one-third. He would not pay toward the death grant, but would pay the whole cost of family allowances. The Government thought that the State should help parents to discharge their responsibility. They proposed that all pupils attending primary and secondary schools under the Education Department should receive, free of cost to the parent, school meals and milk up to the age of 16. Discussing the proposals for old age pensions, Sir William said that at present there were 16 persons over the retirement age to 100 contributors. In 50 years there would be 31. The cost would increase by £155,000,000. That was on the assumption that fertility and death rates would remain as to-day. If our medical services should improve and cures be found for some killing diseases, those figures would be falsified. The net result of the whole social scheme was that in the first

year the taxpayer or the ratepayer would bear 54% of the entire cost. By 1975 he would bear 67%.

Mr. GREENWOOD recalled that a few months ago the House had discussed a national health scheme. That was an essential part of the plan. There was still an enormous amount of preventable disease. He hoped the House would bring that fully into the picture at a later stage. Mr. JOHN GAMSTON regretted that the scheme had been made compulsory. Many people had a conscientious objection to using a doctor. He objected to paying a death benefit of £20. The sole result would be to put up the cost of funerals. He objected to the abolition of the friendly societies, which had adequate arrangements for medical referees and sick visiting.

When the debate was resumed on Nov. 3 Mr. BUTLER said the Government had a positive policy for the young, partly included in the new Education Act. There were also additional benefits under the health plan and under this insurance plan. The Government was spending £57,000,000 of public money on cash allowances for children, excluding the first child, and £60,000,000 on free milk and meals at school. The family was expected to maintain the first child. Family allowances helped to take the strain where the number of children created an insufficiency injurious to health. The Government hoped that family allowances would result in an increase in the birth rate. But confidence made the birth rate rise and the plan as a whole would give greater confidence to our families. If a child entered hospital there would be no charge on the parents under the provisions of the school medical service, but the parents would continue to receive the family allowance. Despite the difficulties of the war the number of children taking their midday meal at school had risen in the last three years from 300,000 to 1,600,000. Little short of 14,000 canteens had been provided to serve 19,000 out of 23,000 schools. Milk had been provided in 27,000 schools. For the "under-fives" the Government would continue for the time being the national milk scheme and the provision of orange juice, cod-liver oil, etc., which had been part of the wartime plan. The Government could not pledge itself to continue the scheme after the war in exactly the same form as now. It asked for time to consider how the needs of the "under-fives" and of nursing and expectant mothers should be met when liquid milk was freely available. Provision in kind would ultimately cover the whole child population. The Government was convinced that it was impossible within the new unified scheme to use approved societies administering only the National Health Insurance part of the scheme.

Sir WILLIAM BEVERIDGE begged the Government to take as its primary aim the elimination of want among children. Col. ELLIOT said a survey carried out in London last June by Lady Mellanby of the teeth of London school-children showed much improvement, which Lady Mellanby attributed largely to the milk scheme of the Milk Marketing Board. The initial work for the scheme had been carried through by the Medical Research Council.

Sir JOHN ANDERSON said that, taking a person "continuously" in employment from 16 to 65 with a normal expectation of life when he retired, 12% of his life from 16 would be spent in sickness or unemployment and during 11% he would draw pension. He added that the Government intended to do its best to ensure that employment in connexion with the new scheme, so far as they were qualified, was provided for full-time officers of approved societies.

The House carried a motion approving the Government's intentions.

Medical News

Sir Joseph Barcroft will give a lecture on "Food and Processing—The Nutritive Value of Processed Food" at a meeting of the Food Education Society on Monday next (Nov. 20) at 2.30 p.m. in the Conference Hall of the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.

A meeting of the Scottish Group of the Association of Industrial Medical Officers will be held on Wednesday, Nov. 22, at 3 p.m., in the Institute of Hygiene, University of Glasgow. Prof. Ferguson will give an address on the resettlement of disabled persons in industry. Time will be allowed for discussion. Members may bring friends, and those interested in industry are invited to attend.

At the meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on Friday, Nov. 24, at 3 p.m., Sir Leonard Rogers will read a paper on "Smallpox—Incidence and Vaccination in India." The discussion will be opened by Dr. C. Killick Millard.

working in the Tropics, and who wish to take advanced work in parasitology and other branches related to tropical hygiene

Unit I—The course in tropical medicine and parasitology is a basic one, covering bacteriology, parasitology and medical entomology as applied to tropical medicine and includes an introduction to nutrition and hygiene as applied to the Tropics. It is well as a systematic review of tropical diseases. Ten weeks of this course are given at the Institute of Parasitology at Macdonald College, Ste Anne de Bellevue. Special prominence is given to laboratory work.

Unit II—The course in the care of ambulatory patients is arranged to give supervised experience in the important diseases common to tropical and temperate climates. Disease will be considered in its various aspects as a community problem. Syphilis, dermatology, tuberculosis, child welfare, paediatrics and haematology will be stressed.

Unit III—Facilities have been arranged for clinical experience in the Tropics under experienced supervision. The facilities of the Demerara Bauxite Company have been made available, and other opportunities will also be arranged in the Caribbean area.

The fee for the complete course will be \$250,000. Units of the course may be taken consecutively or separately as desired. Inquiries should be sent to the Secretary of the Faculty of Medicine, McGill University, Montreal, Canada.

UNIVERSITY OF LONDON

KINGS COLLEGE HOSPITAL MEDICAL SCHOOL

Awards have been made as follows:

Burnes Leo Scholarships R C Read G W C Johnson N Tate Raymond Good Scholarships C S C Roberts J M Carruthers Epsom College Scholarship Norman Lees Anatomy and Physiology Scholarship Divided between Daphne Baker and A N Husain Pathology Exhibition P H A Sneath Science Scholarship G E Langley

WESTMINSTER HOSPITAL MEDICAL SCHOOL

An examination for an Entrance Scholarship in Anatomy and Physiology will be held on Sept 19 and 20. The examination consists of a paper of three hours in both subjects. Candidates should apply to the Secretary of Westminster Hospital Medical School, 17, Horseferry Road, London, S.W.1, for further particulars not later than Sept 5.

UNIVERSITY OF BIRMINGHAM

A course of six lectures for industrial medical officers and others will be held at the Medical School, Hospitals Centre, Birmingham, 15, on the undermentioned dates, at 4 p.m. in the Physiology Lecture Theatre—Sept 11 and 12 "Industrial Dermatitis," Dr E Baylis Ash and Dr Cranston Walker, Sept 18 and 19 "Problems of Vision and Colour Vision," Prof H Hartridge M.D., F.R.S., Sept 25 and 26 "Deafness: its Disabilities Causes, Prevention, and Alleviation," Mr C S Hallpike. The fee for the course is £1 1s, payable in advance to the Secretary of the University, Edmund Street, Birmingham. Nurses engaged in industry are invited to join the course at a fee of 5s.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week there was a big drop in the incidence of the common infectious diseases, notifications of measles, scarlet fever, whooping-cough and diphtheria fell by 339, 326, 324, and 43 respectively. The decrease in scarlet fever and whooping cough was general throughout the country, the number of notifications of scarlet fever being the lowest since the beginning of 1942. The greatest fall in the incidence of measles was in Lancashire, with 83 fewer cases. In contrast to the remainder of the country the south western counties and Wales had a slight increase in measles, the notifications rising from 319 to 366. Eight of the 12 cases of typhoid were notified in Gloucestershire (Gloucestershire C.B. 3, Gloucester R.D. 5).

The notifications of dysentery were the lowest during the present year. The only fresh outbreak of any size was Hertfordshire 18 (Ware R.D. 13), the other big centres of infection being Lancashire with 30 cases, London 19, and Glamorganshire, Cardiff C.B. 12.

In Scotland there was a small general fall in the incidence of infectious diseases. Notifications of cerebrospinal fever exceeded the preceding week's low total by 10. There were 40 fewer cases of dysentery, Edinburgh and Glasgow, with 21 and 24 cases were still the chief centres of infection.

In Eire only 14 cases of measles were recorded, compared with 83 in the preceding week. Twenty-three cases of typhoid were notified, 10 from Dublin C.B., the remainder being isolated cases dispersed throughout the country, this is the second large outbreak of typhoid in Eire during recent months.

Week Ending August 19

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,068, whooping-cough 1,603, diphtheria 398, measles 1,606, acute pneumonia 345, cerebrospinal fever 34, dysentery 248, paratyphoid 5, typhoid 8.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Aug 12.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Paratyphoid A 1, B 5.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ Includes puerperal fever for England and Wales and Eire.

* Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

if the pastille were also made. These investigations showed that penicillin was present in the saliva in large quantities immediately after removal of the pastille and in fair quantities after 15 minutes, and was still present in small quantities up to 30 minutes after removal of the pastille.

2 The experiments described above showed that the penicillin remained active in the gelatin base, and similar experiments repeated on pastilles three months old have shown that there is no apparent diminution in their activity after this period.

3 Investigations on the effect of the pastilles on the bacterial flora of the mouth and throat have produced many interesting results from the bacteriological point of view. It is not felt that these results lie within the scope of the present paper and they will therefore be reported in detail at a later date. It must be mentioned here, however, that it is possible greatly to reduce the number of organisms and even to produce sterile cultures. Numerous control cultures in which penicillinase has been employed to neutralize any penicillin present have shown that any decrease in the number of organisms cannot be due merely to penicillin having been transferred with the organisms on the swab to the culture medium. Further control experiments were performed in which pastilles made of the normal base but without penicillin, and similar pastilles without penicillin but containing citric acid were employed in the same manner as the pastille containing penicillin. These experiments showed that there was no appreciable alteration in the bacterial flora when penicillin was absent from the pastilles even with the excessive salivation evoked by the pastilles containing citric acid. The effect of the penicillin pastilles on the organisms associated with Vincent's infection and on haemolytic streptococci will be dealt with when the treatment of disease associated with these organisms is described.

4 The standard dose adopted is 200 units of penicillin in each pastille, although in cases of acute ulcerative gingivostomatitis (Vincent's type) pastilles containing only 20 units are now employed as this strength has been found adequate in treatment. It is possible that pastilles containing 1 000 or more units might prove even more effective, but limitation in the supplies of penicillin has made it imperative to use the minimum adequate dose.

Method of Employment

Patients were seen daily for clinical and bacteriological control. On starting treatment each patient was instructed to place a pastille in the buccal sulcus, to leave it there until it had dissolved without chewing or sucking, and then to replace it with another. The time taken for the pastille to dissolve varied in different patients, and in general tended to be shorter in the earlier and more acute stages of the infection owing to the greater degree of salivation. The average however was about three-quarters of an hour. Particular instructions were given that a pastille should be inserted last thing at night and that it should be replaced should the patient wake. Great attention was paid to seeing that the patient fully understood the instructions given and the importance of regularity in the taking of the pastilles since it was clear that much depended on intelligent co-operation. Apart from one patient who in error ate 10 pastilles in the first five minutes of treatment, we have received excellent co-operation. The very slightly bitter taste of the pastilles does not appear to be noticed in the presence of an acute oral infection, and even in the normal mouth it is not actively unpleasant.

Cases were divided into the following groups: (1) Acute ulcerative gingivostomatitis (Vincent's type). (2) Acute streptococcal tonsillitis (including scarlet fever). (3) Chronic streptococcal throat carriers. (4) Operations in the mouth and lesions of the oral cavity involving loss of surface. In this group were included post-tonsillectomy cases, fractures of the mandible compound into the mouth, trauma to the bone and mucosa following difficult dental extractions, and ulcerative conditions of the mucosa other than Vincent's.

1. Acute Ulcerative Gingivostomatitis (Vincent's Type)

So far, 25 cases of this type have been treated, including one of glandular fever and three in which the disease, of very severe form was subsequent to a bismuth stomatitis while under treatment for syphilis. The response is best studied under the headings of "clinical" and "bacteriological."

Clinical—All patients became asymptomatic in 24 hours, including several severe cases with pain, insomnia, and general symptoms. At the same time the characteristic fetor had gone. In 48 hours the sloughs on the ragged edges of the gums had disappeared, together with the signs of acute inflammation in the gums themselves. Epithelization of the ulcerated areas

proceeded rapidly and within five days the improvement in all cases was such that treatment was stopped. No patient had any treatment other than the pastilles, and no attempt was made to clean the gum pockets by stringing mouth washes, or instrumentation. Patients have been inspected at fortnightly intervals after the cessation of treatment and no relapse has yet been seen though the shortness of the period during which the investigation has been conducted (three and a half months) clearly does not allow any conclusions to be drawn in this respect.

Bacteriology—Twenty-four hours after treatment had started it was found that the spirochaetes which had previously been present in large numbers were absent, while the fusiform bacilli were much reduced. In 48 hours the fusiform bacilli were further greatly reduced and in many cases absent. In 72 hours both spirochaetes and fusiform bacilli were entirely absent and at this stage it was a common experience to find that the films showed epithelial tissue with very few organisms of any sort. Films made at weekly and fortnightly intervals after cessation of the treatment have shown no evidence of recurrence in any patient. In order to be certain that the clinical and bacteriological improvement was due to penicillin and not to salivation or other mechanical factors one patient with a severe infection was given pastilles made of gelatin and 0.1 g. nipagin only. There was no clinical or bacteriological improvement after 48 hours. Treatment with penicillin pastilles was then started. Films taken 24 hours later showed no spirochaetes or fusiform bacilli. This result coincided with clinical improvement and a rapid cure ensued.

2. Acute Streptococcal Tonsillitis

As already stated it was shown experimentally that it was possible very greatly to reduce the number of bacteria in the normal mouth and throat, and it was therefore evident that the penicillin was at least effective superficially. This diminution in the number of organisms including the haemolytic streptococcus suggested that the pastilles might be of practical value in the reduction of droplet infection. It was doubtful whether it would penetrate deeply enough into the tonsillar crypts to be effective in cases of tonsillitis, but its high diffusibility did not rule out the possibility and it was therefore decided to try the pastilles in a group of patients with acute tonsillitis.

So far 17 patients have been treated, and all showed pyrexia and the presence of Lancefield Group A haemolytic streptococci. In the tonsils there were variable degrees of hyperplasia. Included in this group are four cases of scarlet fever, one in an adult. No salicylates, mouth washes or any other treatment was given. The response will again be described under two headings.

Clinical—The majority of patients became apyrexial within 24 hours and all were apyrexial within 48. There was great relief of local symptoms within 24 hours. This was particularly marked in a severe case of scarlet fever in an adult, who was taking solid food 24 hours after the beginning of treatment, in striking contrast to the controls who were being treated with serum and sulphonamides.

In view of the small number of cases definite conclusions cannot be drawn, but the results certainly seemed to be better than could be accounted for by the chance selection of cases which happened to improve more rapidly than the normal. The results have however appeared striking enough to warrant further work being carried out, and it is hoped shortly to issue a report on a larger series.

Bacteriology—In 7 patients haemolytic streptococci were no longer demonstrable 24 hours after treatment had started. In a further 6 they were no longer demonstrable after 48 hours. Of the remaining 4 of whom three had scarlet fever, one became negative only after six days while the others possessed small numbers of haemolytic streptococci during the whole period of treatment and after it had finished, although the pyrexia had gone in 48 hours and the throat felt normal. The penicillin sensitivity of the organisms in these particular patients was comparable to that found in the others.

It is of importance to mention that in all these cases the usual technique of inoculation often failed to demonstrate

Medical News

Air Marshal Sir Harold Whittingham will give an illustrated address entitled "Aviation's Contribution to Preventive Medicine" on the afternoon of Thursday, Sept 21, at the Royal Institute of Public Health and Hygiene, 28, Portland Place, W.

At the opening of the new session at Westminster Hospital Medical School the inaugural address will be delivered by Sir John Fraser, Bt, Principal and Regius Professor of Edinburgh University, in the Meyerstein Lecture Theatre on Monday, Oct 2, at 3 p.m. Tea will be served in the School.

Dr Robert G. Cochrane, who for nine years has been a missionary of the Church of Scotland and medical officer at the Lady Willington Leprosy Sanatorium at Chingleput, South India, has been appointed Principal of Vellore Medical College, a missionary institution originally founded for the training of women doctors and nurses.

The Association of Scientific Workers has now published its report to the University Grants Committee on the future development of university teaching and research in fundamental and applied science (Oxonian Press, Queen Street, Oxford, 1s). Discussion is confined mainly to the ways in which the rapid extension of scientific knowledge and its application are affecting the universities, chiefly in the physical and biological sciences and related applied branches. The subject is dealt with under six main headings: degree courses, teaching, research, applied science, extra mural activities, and the post-war problem with appendices on salary scales for academic and technical staff.

National scales of salaries for 30,000 nurses employed in mental hospitals in England and Wales are recommended in the report of the Mental Nurses Subcommittee of the Nurses' Salaries Committee. Some of the salaries are: women, from £380 to £600 with emoluments worth £200 for the matron of a mental hospital or institution of 670 beds or over which is a training school, staff nurses, £120, rising by £5 a year to £160, with emoluments of £90. Men, non-resident chief nurse of a hospital of 670 beds or over which is a training school, £450 to £620, plus £5 emoluments (resident £315 to £485, plus £140 emoluments), staff nurse, 95s a week, rising by 5s to 110s if non-resident, with emoluments to the value of 2s weekly, and 62s 6d rising by 5s to 77s 6d, with emoluments valued at 34s 6d weekly if resident. Among other recommendations are new appointments to posts above the grade of ward sister or charge nurse to be filled only by State-registered nurses, free medical and surgical in-patient treatment, uniform free of charge, one complete day off duty a week and 28 days' annual leave. The Rushcliffe Committee have now to report on superannuation and pension rights.

In St Dunstan's Hospital wards there are, regrettably, some wounded men just returned from the fighting in France, who will, to quote Sir Ian Fraser in his annual report, "learn to be blind." For nearly thirty years St Dunstan's has been teaching the blind a new "design for living," how to look after their own personal needs, to read, to typewrite, to follow certain occupations such as carpentry, boot repairing, etc., and even to swim and ride. St Dunstan's method is to give comfort and hope in the early ages of blindness, then preliminary training after health has returned, and finally vocational and professional training to those who are fit for it. Veterans of the last war (1,800 survive) are ill being looked after, and some hundreds of men blinded in the recent war, including Canadians and Americans, have passed through St Dunstan's. Sir Ian adds no appeal in so many words, that St Dunstan's is a cause which to-day more than ever deserves generous support.

A report of the midwifery cases attended by the Queen's Institute District Nursing and by village and other nurse-midwives in 1943 states that the shortage of domestic help has resulted in a larger number of patients entering hospital, and therefore the number of domiciliary cases was fewer by 4,723. The maternal mortality rate, though slightly higher than in 1942, was the second lowest on record, being 1.35 per 1,000 live births. The total number of cases attended where no doctor was engaged was 84,459; 22,771 of these were in primiparae. Medical aid was summoned for the mother in 28,721 cases (34.0%)—that is, during pregnancy 5,631 (6.8%), during labour 19,863 (23.5%), and during puerperium 3,167 (3.7%). Medical aid for the infant was summoned in 5,072 cases (6.0%). The report adds that as ill-health may be due to domestic circumstances of the patients the need for adequate home visiting during the antenatal period cannot be over-emphasized. The integral part of any antenatal scheme must be close co-operation with the doctor, for the summoning of whom in the event of illness or emergency the midwife is responsible.

Letters, Notes, and Answers

ANY QUESTIONS?

Injectations for Osteo-arthritis

Q.—*Procaine is successfully used for intramuscular injection into painful spots in fibrositis and allied conditions. Has it ever been used for injection into the hip joint in intractable painful osteo-arthritis and with any success? Granted full sterile precautions are there any contraindications to this treatment?*

A.—Various solutions have been injected into osteoarthritic joints with, at the most, short-lived success. Procaine gives transient loss of pain, and is quite useless for this condition. In fibrositis the action of the fluid is largely mechanical, and saline will do equally well except that the immediate pain is greater, and, therefore, massage and exercises are carried out less willingly.

A Midwifery Anaesthetic

Q.—*I have heard that a new midwifery anaesthetic is being tried out which will render Minnit gas apparatus obsolete for midwives. Can you tell me if this is true and what it is?*

A.—The Minnit apparatus for analgesia has rendered yeoman service, but it suffers from the defect that the percentage of N₂O delivered to the patient varies with the depth of respiration. The deeper the respiration the more the gas is diluted with air. Recently experiments have been carried out with nitrous oxide delivered through a Venturi jet. The percentage of N₂O in the resultant mixture here remains substantially constant whatever the flow of gas. The Venturi jet principle has been applied to oxygen therapy, and an explanation of its working is to be found in an article by S. L. Cowan and J. V. Mitchell, "Improved Equipment for Oxygen Therapy" (*British Medical Journal*, Jan. 24, 1942, 1, 118).

Removal of Tonsils by Diathermy

Q.—*Is it possible to use the galvanic current to destroy infected tonsils by means of "needling," as for small growths, etc.? If so I should be grateful for details of technique, as I do not find these subjects mentioned in the textbooks.*

A.—The only effect of the galvanic current would be to produce a contraction of the muscles of the pharynx, a sufficient reason for the silence of the textbooks. Diathermy consists in passing a high frequency current of great power through the body. Used for surgical purposes the small electrode generates intense heat in the tissues in the immediate neighbourhood. Repeated applications can be used for the destruction of growths and similarly for the destruction of tonsils. The modern unipolar apparatus is more convenient in practice, as it is not necessary to use a second large electrode applied to an indifferent area. The procedure is painful, so that an anaesthetic is necessary, but ether must be avoided. The late Dr. Dan McKenzie described the procedure fully in *Diathermy* (Kegan Paul), and a description of diathermy may also be found in *The Nose and Throat* (Arnold) by the late Charles A. Parker.

Vagal Attacks

Q.—*A busy and active practitioner aged 69 who smokes about 12 cigarettes a day, frequently has, after morning surgery followed by a cigarette, and occasionally after a hot bath or a game of golf, a feeling of faintness with sweating and slow pulse (48), but with no loss of consciousness. A cardiologist finds heart and B.P. normal and suggestive of a younger man. Normal pulse 60 to 64. He calls it "vagus vagans" and can only suggest a holiday. The patient has some spondylitis of neck and osteo arthritis in fingers and elbows. What is the pathology and treatment?*

A.—Faints or syncopal attacks may be due either to diminution of the venous inflow to the heart, as a result of active or passive dilatation of portions of the vascular bed (vascular syncope), or to

where both arm wounds were carefully cleaned and the soiled tissue excised; the wounds were packed with sulphathiazole and proflavine, 1%, with vaselined gauze, and the arms put in plaster. As her condition was deteriorating, the wounds of the back were washed with half-strength dettol, dusted with sulphanilamide powder and proflavine, and a vaselined gauze roll was applied. Many pieces of glass were removed from the gashes, most of which had penetrated the superficial fascia only. An intravenous drip was put into the long saphenous vein in the groin. The total time on the operating table was 2½ hours. On return to the ward she was given 2 pints of blood and 2 pints of glucose-saline within the next 12 hours. Her condition on the following day was quite satisfactory, considering her physique—temperature 99°, pulse 120, respirations 28. On account of her emphysema she was given breathing exercises and, anticipating sepsis of the wounds, she was put on sulphapyridine, 1 g. 4-hourly. By the fifth day after operation her condition began to deteriorate; she was eating little and became drowsy. There was no anuria or oedema of the feet. On the sixth day her temperature began to climb to 100°; she complained of severe abdominal pain, and the pulse, having been down to 90, rose to 110, and the respirations to 35. She had signs of a consolidation at the base of the right lung and the abdomen was distended. She died in the afternoon of the seventh day after operation with gross dilatation of the abdomen.

At necropsy all the coils of gut were distended from paralytic ileus, and there was oedema of the lower lobes of the lungs. After removal of the plaster the arm wounds were absolutely clean and appeared just as they had left the theatre. The wounds of the back were surrounded by nothing more than a small area of oedema with a little reddening, and many of the wounds were oozing a serous discharge—a picture of indolence. The gut was grossly distended, as it had been just before death, from paralytic ileus. Histological examination of the liver showed marked cloudy swelling and fatty degeneration, with toxic changes in the spleen.

In retrospect several points stand out about this case. First, our experience, and that of other hospitals in the district, has shown that it is most unwise to allow an operation to extend for more than one hour in these very shocked patients. After an hour their blood pressure falls and their general condition deteriorates very rapidly. One should curtail one's activities within this time limit. Our careful surgical toilet of the extensive arm wounds probably cost the patient her life, since as the wounds were unchanged after seven days one can assume that the patient's resistance was very low, and there was no attempt at repair or reaction against the bacteria which must have been present. Secondly, I think she was taken to the theatre too soon. We gained the impression that the tendency is to operate too early—before the patient has recovered from profound shock, both psychological and cardiovascular—rather than too late. We allowed far longer for recuperation in the later cases of the series, with improved results. Thirdly, the object of the plaster was to immobilize the soft-tissue wounds, as advised by Trueta, in order to avoid pain and to prevent bacterial spread via the lymphatics. Both these objects were achieved, but psychologically I think it was unsound to imprison both arms of this type of patient, which made her feel still more helpless.

Case II (Mr. Y., aged 63)

This patient was admitted on July 3, 1944, with multiple cuts of the back and arms, which were very dirty, with earth and grit driven into the depths of the wounds. He was very shocked, with blood pressure 75/50, but conscious and able to drink. He was therefore given hot sweet tea and 1¼ gr. morphine, with A.T.S. 6,000 units and A.G.S. 22,500 units intravenously. It will be noticed that the latter was in accordance with the new instructions of the E.M.S. Memorandum, and a considerable increase on the dose given in Case I. His wounds were wrapped in sterile towels and he was left for a time, since his condition was considered to be almost hopeless and more promising cases demanded attention. About an hour after admission he was given 1 pint of plasma intravenously, followed by 3 pints glucose-saline in the next 12 hours. On July 4 he had not passed urine for 24 hours and, although the bladder was not palpable above the symphysis pubis, he was given carbachol 0.5 c.cm., and the dose was repeated half an hour later. Following this he passed about 10 oz. of urine. His condition next day had considerably improved, and his blood pressure rose to 100/80. His wounds had been entirely untouched apart from wrapping in the sterile towels. In view of our previous experience the correct course of treatment was debatable. We decided not to take him to the theatre; instead, his back was merely washed in the ward with dilute dettol, followed by half an hour's radiant heat, after which it was dusted with sulphanilamide powder, vaselined gauze and proflavine were applied, and the sterile towels were

replaced over the wounds. The next day (72 hours after admission) his blood pressure had risen to 120/80, and it was decided to take him to the theatre. There a large piece of wood, 4 in. long and 1 in. in diameter, was removed from his back and a few pieces of glass were taken from the cuts, but no extensive exploration was carried out. His back was sprinkled with sulphathiazole and proflavine, 1%, and he was returned to the ward within 15 minutes, having had under 0.75 g. of pentothal. I feel that this visit to the theatre was superfluous, apart from the removal of the large piece of wood, which we had not been able to do in the ward. As he was a very fat and flabby man of 63, he was given breathing exercises daily. On July 6 he started having hot normal saline baths, which relieved his pain considerably. After the first day he was allowed to sit up in the bath and use ordinary soap, which he did with very great enthusiasm. His progress from then onwards was highly satisfactory; every day saw marked improvement. After the baths his back was dusted with sulphathiazole, and dry dressings were applied, kept in place by three many-tailed bandages. On the seventh day, at his own request, he was transferred to another hospital, where his wife, also an air-raid casualty, had been taken. Nearly all the small cuts of the back had healed, leaving five or six of the larger ones a little septic and gaping, the worst being a gash some 1½ in. wide.

He reported again on Oct. 3. The back was then completely healed.

TABLE I.—Glass

Description	No.	Remarks	Deaths
Lacerations of face, scalp, and neck	77	19 T	—
Perforating wounds of eye	15	5 cases bilateral	—
		2 T	—
Cut hands	9		—
Severe multiple lacerations	6	1 T	1
Other injuries	5	—	—

Any patient may appear in two or more tables.

B. Bomb Splinters

A striking feature was the low incidence of penetrating wounds of the body cavities. We did not have a single penetrating wound of the abdomen; and there was only one of the chest—giving rise to a haemopneumothorax. This is excluding two patients with multiple perforations who died a few minutes after admission, the cause of death being unknown, as necropsies were not performed. There were two perforating wounds of the cranium. This contrasts with the injuries of bullets and heavy bomb splinters. I think it is due to the shape of the fragments, which tend to be small flat pieces of metal, often about the size of a halfpenny, or smaller, and the thickness of a sixpenny piece. These disks have a high coefficient of friction and probably a low velocity. The longest track we discovered was some 5 in. through fat and muscle, in the region of the hip, and this patient had been lying within 20 yards of the crater edge.

Occasionally the bomb fragments are large tangled masses of crumpled sheeting, weighing a pound or more, and these may cause very severe injuries. One man hit by such a fragment had his right humerus shattered and some 6 in. of the triceps muscle torn away; another had his thigh nearly severed, with severe comminution of the femur.

Apart from the small splinters at very close range and the massive fragments mentioned above, the bomb splinters did little serious damage. There were six cases of injuries by wood splinters, which were confined to the soft tissues and did not penetrate to any of the body cavities. One patient had a large piece of wood driven between the head of the radius and the ulna in an antero-posterior direction and projecting 5 in. each side of the arm, yet, miraculously, no important structure was damaged.

TABLE II.—Bomb Splinters (24 Cases)

Description	No.	Remarks	Deaths

Wood splinters	6	1 T	—

INJECTION TREATMENT OF VARICOSE VEINS

'Ethamolin' as a sclerosing agent has less tendency to any reopening of the vein. The outstanding merit that, while it produces the firmest and most adherent thrombus, accidental leakage of the solution into the tissues around the vein will not cause sloughing. Pain following the injection is very infrequent, and there is considerably less tendency to any reopening of the vein. 'Ethamolin' is a stable chemical compound of consistent potency ensuring uniform results. It is powerfully bactericidal, and thus it reduces to a minimum any risk of introduced infection from the injection.

ETHAMOLIN

BRAND OF ETHANOLAMINE OLEATE
2 cc. ampoules in boxes of 6 and 100 Bottles 15 cc. and 33 cc

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434.

ACETARSOL VAGINAL COMPOUND

— BOOTS —

VAGINAL ANTISEPTIC

Acetarsol Vaginal Compound—Boots is a preparation containing acetarsol with boric acid and carbohydrate for local application in the treatment of leucorrhoea associated with *Trichomonas vaginalis*.

Clinical results have shown that Acetarsol Vaginal Compound—Boots is superior to vaginal douches, and the patient is spared much inconvenience on account of the ease with which treatment can be carried out.

Supplied in tablets each containing
4 gr. acetarsol

Bottle of 25 tablets - - 3/11

Bottle of 100 tablets - - 11/8

MEDICAL DEPARTMENT

BOOTS PURE DRUG CO. LTD NOTTINGHAM

Dr. Jones went on to criticize Schindler's classification of gastritis, first, because it was a mixture of cause and description, and, secondly, because it did not consider superficial chronic atrophic, and chronic hypertrophic gastritis as separate entities, but merely as phases of one disease process. Dr. Jones preferred the following classification:

Unknown cause—Non-specific gastritis

Naturally the full description should be given of the gastroscopic changes, but he did not advise subdivision on the descriptive basis. The points he looked for were degree of activity, position, thickness of mucosa and associated mucosal changes. Of 335 cases of haematemesis and melæna in which early gastroscopy had been frequently done, only 7 were diagnosed as active gastritis. He considered non-specific gastritis an important entity but a comparatively uncommon disease. Pathologically there was an important discrepancy. Atrophic pyloric gastritis was commonly seen microscopically but was very seldom diagnosed gastroscopically.

Radiological Diagnosis

Dr. MATHER CORDINER said that the radiographic changes which were to be seen in gastritis might be considered under four headings: (1) In gastritis there was an alteration in the slipperiness or stickiness of the mucosal surface. One got the impression on from the x-ray picture that the surfaces were sticking together and that they were slowly separated from each other by the opaque medium as it flowed slowly over the mucous membrane. (2) A mild degree of gastritis stimulated the autonomic motility mechanism of the mucous membrane so that an unstable and rapidly changing mucous membrane relief especially noticeable in the pyloric region was obtained. (3) The softness, mobility, flexibility and deformation and obliteration of the normal mucosal folds were important characteristics. Pathologically altered folds showed a loss of flexibility, a decrease of movement on palpation and were less easily deformed and smoothed out by pressure and by stretching. (4) In a large proportion of cases the basic pattern of the mucosal relief was not altered in gastritis. Large folds did not signify hypertrophy, a term which was only rarely justified radiologically in describing this condition. He summed up by saying that a radiological diagnosis of gastritis was possible when the mucosal relief was abnormal and was accompanied by rigidity of the folds. A diagnosis of hypertrophic gastritis was possible only in the presence of a polypoid hyperplasia of the mucosa. There were no characteristic findings which enabled the radiologist to diagnose atrophic gastritis.

A Condition rarely Diagnosable

Dr. P. E. THOMPSON HANCOCK said that of the various types of gastritis recognized clinically, histologically, and gastroscopically only two, apart from the acute forms, had a recognizable syndrome—namely, alcoholic gastritis and chronic diffuse atrophic gastritis. The first of these could often be recognized, though it was now on the wane. In the second the patient complained of fatigue, anorexia, and loss of weight. Dull epigastric discomfort rather than abdominal pain was the usual complaint, and was not alleviated by alkalis. Nausea and vomiting were exceptional. On examination there might be some anaemia but there was little or no epigastric tenderness. If with this clinical picture there was no radiological evidence of gastric abnormality and no free acid was found in a fractional test meal, a diagnosis of chronic atrophic gastritis was justifiable.

In his experience, radiology had not helped in the diagnosis of gastritis and had often, in fact been misleading. He had worked with several radiologists who had taken great interest in the correlation of the radiological and gastroscopic appearances, but he thought he could safely state that they now very rarely made any pronouncement about gastritis, confining their

comments to the size of the gastric rugae. He was afraid also that the gastroscopic diagnosis of gastritis was not irrefutable. He had made just over 1,400 gastroscopic examinations, and had diagnosed gastritis in about 21%, but whereas in his first 300 cases he diagnosed hypertrophic gastritis 18 times or in 6% of the cases, in his last 300 he had diagnosed it only twice, or in 0.66%. This was mainly due to the fact that the normal stomach had a far wider range of size and distribution of folds and degree of visibility of the area gastrica than was formerly recognized and the criterion of the diagnosis of hypertrophic gastritis must be the presence of definite inflammation. In all other forms of gastritis he found that his percentage frequencies were fairly constant throughout the series.

In short he believed that gastritis was rarely diagnosable as a clinical syndrome and that gastroscopy was the only investigation which enabled the positive diagnosis to be made. But the gastroscopic diagnosis was not infallible, the tendency being to diagnose gastritis too frequently owing to insufficient allowance being made for the great variations normally occurring in the gastric mucosa.

Emotional Reactions

Dr. MORTON GILL described some of the outstanding observations concerning gastritis which had been made during the last century down to the record series by Wolf and Wolff, who had shown that the gastric mucosa could reflect mental changes to an extraordinary degree. Thus with anxiety or resentment there were swelling and congestion, increased motility and increased excretion of HCl. Fear produced pallor of the mucosa accompanied by a diminished excretion of acid. From this it followed that while gastritis might be the result of direct damage to the mucosa by a local irritant, equally, visible mucosal changes initially vascular in the nature of alterations in the blood flow might be of central origin. Thus when it came to radiological or gastroscopic diagnosis of chronic gastritis it was at present difficult if not impossible, to be certain whether some at least of the mucosal changes might not be an expression of anxiety on the part of the patient, concerning either the examination itself or its results. It seemed to him that understanding of gastritis would be advanced perceptibly when it became possible safely to perform biopsy upon the gastric mucosa and to obtain a specimen of sufficient quality to allow histology of the living mucosa. He also suggested that the time had come to abandon the term "chronic gastritis" and to use instead purely descriptive terms—for example, mucosal hypertrophy, mucosal atrophy, mucosal hyperaemia, etc.

Sir HENRY TUDY criticized the classification of Schindler, in particular his use of the term "hypertrophic gastritis". He agreed with what Dr. Hancock had said that chronic catarrhal gastritis was the commonest form, but had no recognizable syndrome and probably was often symptomless. He also referred to Army experience and handling of so-called gastritis cases, the loose use of the term "gastritis", and the advance towards precision, evidenced in the present discussion, as compared with what was held even as recently as four years ago.

Dr. J. JACQUES SPIRA submitted what he called a simple but comprehensive classification of chronic gastritis. Direct causes were inflammatory processes associated with increased acidity and chronic peptic ulcer and accounted for chronic superficial or catarrhal gastritis produced by mild repeated irritation by mechanical, thermal, or chemical factors or the swallowing of purulent material and chronic hypertrophic gastritis produced by severe repeated irritation, both being subject to immediate relief and cure by the removal of the offending agent. Indirect causes were degenerative processes associated with decreased acidity and gastric carcinoma, and gave rise to atrophic gastritis with primary factors associated with deficiency diseases, and secondary factors associated with other pathological conditions, calling for appropriate substitution of treatment.

Mr. JENNINGS MARSHALL, who was unable to be present, sent a contribution to the discussion in which he described primary and secondary gastritis, the latter arising as a generalized condition from any chronic obstruction. With regard to primary gastritis he made the interesting point that

much better," his temperature came down, and the inflammation of the varicella spots began to subside. In 48 hours the vesicles had dried up and the surrounding redness faded; in fact the rash seemed to abort and, reach in 2 days the condition usually seen after 5 or 6 days. The herpes ran a typical, somewhat severe course, the inflammation of the upper lid and swelling of the conjunctiva, with inability to open the eye, being his chief complaints. There was no definite ulceration of the cornea, but he was unable to open his eye for a fortnight owing to oedema of the upper lid, and when this subsided the scabs on the upper lid limited its movement until they separated. The neuralgic pain and altered sensation in the frontal area cleared up slowly in about 6 weeks from the start. In this case the herpes of the fifth nerve developed to its full extent before the varicella rash appeared. I was led to give sulphathiazole because a month previously I had seen a very severe case of chickenpox in a man of 37. He had a rash from head to foot and felt very ill. His temperature rose to, and remained at, 105° F. for nearly 12 hours. After a few doses of sulphathiazole he felt "a new man," and within 24 hours his temperature fell to normal and remained so in spite of the many infected spots.

Dr. MARY BARROW (Birmingham) writes: I have only met one case of these two occurring in the same patient concurrently. On Aug. 3, 1944, a man aged 59 had the eruption of herpes zoster in the mid-thoracic region—a moderately severe attack. The chickenpox vesicles appeared on Aug. 8 and he had a widespread rash by the next day. He does not remember whether he had chickenpox in childhood.

Ascorbic Acid in Treatment of Gums

Dr. K. MALIK, L.D.S. (London, N.1), writes: I was more than ordinarily interested in the article on ascorbic acid and its value in the treatment of gums (Aug. 19, p. 239). Some years ago I was asked to use the ascorbic acid tablets presented to me on a special case or cases. I did so and reported its uselessness to the manufacturers. I would, however, point out that the title "Bleeding Gums" is misleading, as ascorbic acid is of definite use in accelerating healing after extractions. A further point is this: What do the authors mean by a "dummy" tablet? Do they mean one made mostly of sodium bicarbonate? There is a school of thought that says "alkalis will cure any dental disease, including gum disease."

Meigs's Syndrome

Capt. C. BORG, R.A.M.C., writes from the Connaught Hospital, Knapthill: In the article on Meigs's syndrome by Clay, Johnston, and Samson in the *B.M.J.* of July 22 the authors state that previously only one case of this syndrome has been reported in the last 20 years in the British literature—namely, the case by Gild in Dec., 1943. I beg to point out that this statement is incorrect, as I reported a case in the *Journal of Obstetrics and Gynaecology of the British Empire* in Dec., 1941.

Pethidine in Asthma

Dr. F. BEDO HOBBS writes from Farnham, Surrey: I should like to send a note of warning in reply to Dr. Douthwaite's letter (Aug. 5, p. 200), wherein he recommends injections of pethidine for stubborn cases of asthma. I recently saw a woman with persistent urticaria and asthma for whom this treatment was recommended. It gave her so much relief accompanied by a sense of well-being that she had been in the habit of giving herself three injections of 50 mg. daily for several months. Just before coming under observation she had been behaving queerly and had, according to her sister, had twenty-six injections of 50 mg. in the course of three days. When admitted to hospital she was very excitable and talkative and completely irrational and disorientated. Although the pethidine was immediately stopped and sedatives given, she remained in the same state for a week, after which she gradually became quieter and less confused, although she relapsed at times for a further three or four days. As pethidine is now being prescribed more frequently the fact that this drug is not included under the D.D.A. and can be obtained by anyone without a prescription makes one realize that it should not be ordered lightly and without explaining the risk of habit formation to both patient and relatives.

Masturbation in Men

Dr. J. LUXFORD MEAGHER (Victoria, Australia) writes: In your column "Letters and Answers" in the issue of the *Journal* for Jan. 1 appears a note on the subject of masturbation in men. I have read the reply with frank feelings of disgust. The answer concerns the course to be followed by a young man of the Forces who feels disposed to masturbate. He is to be told to adopt this practice deliberately, and while "not attaching any sense of guilt to the act" should not do it too often, and "only as a relief for unbearable sexual tension." Acting on these lines he is assured that his health will not be impaired nor will his future sexual life be prejudiced. The end, of course, cannot possibly justify the means. Abstracting from the moral aspect, I am at a loss to know why, if the practice is intrinsically harmless, a restriction should be placed

upon its use. I deny the possibility of frustrating a physiological function in its very nature without harm resulting. Is not the danger of habit formation to be expected? Can the practice be taken up and relinquished at will? I know of at least one case in which the husband, though living under the same roof as his wife, was addicted to the vice. It is precisely those who are weak of will or whose wills are not yet fully developed to whom it appeals. Surely an act universally condemned throughout the ages cannot suddenly, owing to any "trend of opinion," become permissible. Further, it is not within the power of the individual to withhold the consciousness of guilt from any act which his conscience disapproves. The remedy for all unnatural urges is strenuous resistance, reinforced by prayer; also sublimation of those urges, as the answer rightly suggests, by athletic and intellectual interests. To propagate the notion of unnatural vice as the answer does is shocking. To suggest that medical men should lend themselves to the task is the limit.

Corticotrophic Hormone

Dr. R. E. HEMPHILL (Bristol) writes: As a result of the article by Reiss and myself published on Aug. 12 (p. 211) a number of inquiries have been made as to where this preparation may be obtained. So far as I know corticotrophic hormone is not as yet available commercially: The hormone we used was a laboratory product made available through Messrs. Organon.

Agricultural Rehabilitation of War Casualty Cases

G. D. G. writes: According to information received at the Chinese Embassy in London, the Chinese Ministry of War has opened a rehabilitation centre for war-damaged men in Szechuan Province. The first corps of 1,000 soldiers has arrived there and the men are being distributed for work on the land. Several thousand more helpers are required on farms in Britain for the corn, potato, and other harvests. The call-up of men for the Forces is said to leave many farmers facing serious loss, more especially as the embargo on Eire will interfere with the importation of Irish labourers. We shall be dependent on volunteer harvesters from our town-dwellers if these vital crops are to be gathered in. Farmers are offering good pay, food, and accommodation, and the healthiness of open-air life provides an additional advantage. That is one side of the picture. The other side concerns the thousands of soldiers who have become convalescent from their war injuries but who are as yet unfit to resume their former occupations. Their minds, bones, and muscles have been damaged and require to be made good again in as efficacious and natural a way as possible—by occupational therapy. The instruments and appliances of physiotherapy are most valuable up to a certain stage; but, after injured parts have again been induced to function, routine exercises in hospital lack the stimulus of productive work. Though the summer session is well under way it may be possible to accelerate arrangements through the three Service channels and the Ministry of Agriculture to put convalescent soldiers on the land. Whether as cultivators, harvesters, tractor drivers, carters, dairymen, poultry keepers, there are many roles they could fill for the mutual benefit of themselves and the farmers. There is no calling other than agriculture that would so satisfactorily bring these men back to health and fit them for return to civil life, in addition to the important factor of augmenting the national food supply. One has only to enter our hospital wards and see the number of tragically neurasthenic and shell-shock cases to realize the clamant need for treatment by recuperative occupation. There are also few physical injuries that do not favourably respond to functional use in health surroundings. The varied work of farm life and the peacefulness of it all never fail to interest men who have come through the inferno of modern warfare.

Chronic Vasomotor Rhinitis

Mr. J. BERNSTIEN (Liverpool) writes: I was extremely surprised at the reply which was given to the question concerning chronic vasomotor rhinitis (Aug. 12, p. 230). This is an accepted well known allergic condition, and local treatment is of only palliative effect and should consist of cauterization to any sensitive points found in the nose, which are usually at the anterior or posterior ends of the inferior turbinates and tubercle of the nasal septum, or by nasal ionization with zinc. But these local procedures are of very little value and should only be supplementary to treatment by desensitization and avoidance of the allergen concerned.

Correction

The first line of the fourth paragraph of the annotation headed "Seeing is Believing" (Aug. 26, p. 281) contained a misprint. I should have read "The first interest of a commercial firm is in its commerce."

Disclaimer

Dr. C. O'DONOVAN (Burbage, Hinckley) asks us to state that he had no knowledge that his name would be published (as it was in a provincial evening paper) in connexion with the supply of penicillin to a patient, nor did he give permission for it to be used.

Your most recent correspondents (Oct. 28 and Nov. 11) find fault with the procedure from the point of view of the Catholic Church (whose dictates on other obstetric matters are not accepted by the profession at large) or on grounds that it "offends" the marriage bond, and, apparently, on grounds of some vague ethical horror of semen being emitted anywhere other than in the vaginal canal. Other correspondents throughout the year have asserted that any woman who is artificially inseminated will later "draw away" from her husband; that the child "will come between" them; or that the husband will become jealous of the child. Indeed so many possible emotional disasters are portrayed that one wonders if they exist more in the fears of the critics than in their actual experience. There must be many patients who would share the feelings of such critics, but they would not, naturally, be found among those who seek advice upon the matter.

Practitioners experienced in dealing with sterility know how very deeply some women feel the deprivation of child-bearing. Their barrenness may be a source of such humiliation and depression as to be hardly credible to an outside observer. When such a woman is married to a sterile husband, in these days it is almost inevitable that the husband raises the question of artificial insemination; nor is it at all uncommon for a sterile man to wish that his wife should not, through his misfortune, be denied the fulfilment of her deepest desire. Out of respect for some of these husbands with whom I have spoken, I think it only fair to say that many of them express feelings totally dissimilar from those of your anxious correspondents. It has been often a privilege to see the tenderness and generosity with which such men may approach the subject. "I would give anything on earth for my wife to have a child of her own making" has been said to me; and, again, "How could I possibly love an adopted child as much as one born of the woman I most love?" How could such an attitude do anything but arouse gratitude and appreciation in the wife, and thus, enrich their marriage in the deepest way? If "organized religion" has no use for marital bonds of this sort, it may well be religion itself which will be found wanting.

Other objections raised against artificial insemination may apply to some cases, but not necessarily to others. Not every patient feels the procedure to be offensive or humiliating; as with most gynaecological work, this depends as much on the attitude of the practitioner as of the patient; nor do they fail to appreciate the good will which the donorship (gratuitous, at any rate, among clinic patients) has implied. Nor, indeed, need the husband be necessarily the "loser." I know of one husband, impotent as well as sterile, who has had his self-esteem most wonderfully enhanced since his wife has (unknown to other people) given birth to such a child.

No practitioner would ever claim that the procedure of artificial insemination can be lightly undertaken or have any wide application in this country. But surely it is time that the medical profession adopted a more realistic attitude towards it. Furthermore, since no two people feel alike in matters such as sexual intimacy or child-bearing, it surely behoves more fortunate people not to deny a barren woman the achievement of her greatest desire or to criticize her husband's generosity in helping her to reach it. Although such ways of feeling may be personally unacceptable to a practitioner, he could refrain from condemning aspirations admittedly outside his own philosophy.—I am, etc.,

JOAN MALLESON.

London, N.W.1.

SIR.—While agreeing with Dr. Newsholme that the medical profession needs to keep a careful eye on the ethics of insemination, I am frankly appalled by the attitude to masturbation which his letter reveals. Apparently he believes that a married couple should deny themselves the fulfilment of parenthood unless ejaculation takes place through stimulation produced by friction of the penis with the vagina. If this is not possible and the semen is produced by friction with the fingers, he asserts the act to be "so besmirching as to make it wrong." Wrong in the eyes of what sort of deity, I wonder!

One does not expect a man of Dr. Newsholme's eminence to perpetuate the unbalanced emotional attitude to masturbation which is the basis of so many neuroses. One should properly distinguish between masturbation as a habitual expression of sex life and masturbation as an occasional resource when

there is prolonged deprivation of normal or accustomed sex life. In the one case it is an immature self-centred act, betraying an infantile personality. The addict needs to be freed from the fixations which are keeping him at that level. In the other case it is the deliberate choice of a free adult personality, and no stigma of any kind need attach to it. In the case of the married couple aforesaid the desire to produce a child at the cost of a mechanical intrusion on their emotional life is a proof of their mutual love, which nothing can "besmirch"—I am, etc.,

Birmingham

R. MACDONALD LADELL.

Physiology of the Vagina

SIR.—I have read your annotation on the physiology of the vagina (Nov. 11, p. 635) with much interest. Will you, however, forgive me for a criticism? You say: "The Fallopian tubes, uterus, and vagina are all developed from the Müllerian ducts. It is therefore not surprising that the tubes and vagina resemble the uterus in that they react to ovarian hormones." Even if the first of these sentences be entirely correct, which I doubt, why should we therefore expect that the organs concerned would react to ovarian hormones? Such reactions are not confined to structures of Müllerian origin, nor within the Müllerian system are the reactions alike in nature or equal in degree. Apart from the supposition (which I do not accept) that the vagina is wholly derived from the Müllerian ducts, it may be borne in mind that the response to oestrogen does not cease abruptly at the introitus.

I would not wish to trouble you with a letter on the subject if it were not that the biological actions of sex hormones comprise a new branch of knowledge of which we are only now working out the principles; at this stage expectations and assumptions may be unreliable guides.—I am, etc.,

The Chester Beatty Research Institute,
Royal Cancer Hospital.

HAROLD BURROWS.

Supplement to Breast-feed

SIR.—Dr. Lydia Fehily's interesting article on human-milk intoxication (Nov. 4, p. 590) prompts me to call attention to a fairly prevalent human-milk deficiency condition, increasingly common nowadays, which, while not so directly lethal to the baby, is serious enough to merit early diagnosis and treatment. I am referring to protein deficiency in breast milk. It is my impression that about every one in six "new" babies suffers from it in the welfare centres I attend. The clinical picture is as follows. A worried mother explains that the baby appears always to be hungry. It is restless, sometimes even during sleep, of which there is relatively little because it cries so much and appears generally irritable. The baby feeds voraciously but does not appear satisfied. The general wretchedness of both is usually apparent. Test-feed results sound reassuring, the milk being adequate or even abundant. The pathognomonic answer usually requires to be elicited carefully; sometimes visual evidence is necessary. It is that the stools are dark green and contain curds, sometimes slime, and, if the condition has been present long enough, sore buttocks in addition. The baby has gained very little if at all.

If food fads are persisted in under present-day rationing conditions, and these are very common, such as refusal of cheese and fish and sharing the pint of milk, it is not surprising that the breast milk should contain insufficient protein. Further, in infant welfare centres most of these cases are seen in very young babies, so that the mothers are still not recovered from the effects of childbirth, or, as I recently found, the condition was present in an exceptionally well-fed woman of frail type who was still having uterine haemorrhage after six weeks.

Treatment consists of giving minimal amounts of supplementary cow's milk, which fortunately is rich in protein. For instance, a baby of a month or so usually has all its protein requirements restored by one tablespoon of cow's milk three times a day. Maximum requirements at any suckling age are no more than four tablespoons four times a day, after the breast, assuming there is adequate secretion. Apart from larger amounts being unnecessary, it is often strategically inadvisable to give encouragement to the idea that the bottle feeds are superior to the breast, the magical effects in such cases being so striking that preparatory explanation is very necessary. Too often such babies are soon weaned, with the explanation that the mother's milk "can't be any good," and

RETINAL DETACHMENT: A SERIES OF 78 CASES IN THE MIDDLE EAST FORCE

BY

H. B. STALLARD, M.B.E., M.D., F.R.C.S.

Major, R.A.M.C.(T.A.); Assistant Eye Surgeon, St. Bartholomew's Hospital

In the war of 1914-18 the treatment of retinal detachment was a failure, and indeed this was so up till 1929, when Jules Gonin (Switzerland) described to the International Congress of Ophthalmology in Amsterdam his successes obtained surgically by sealing a retinal tear or tears and evacuating the interretinal fluid by means of puncture with a galvano-cautery. Before this discovery very few cases of retinal detachment underwent improvement and spontaneous recovery; such were quite exceptional.

Gonin's principles still hold good to-day, but the operative technique has changed. Accurate location of the retinal tear or tears in relation to the outside of the sclera is essential. The edges of the retinal tear and the choroid overlying this site are rendered adhesive by electro-coagulation. This is effected through diathermy, applied either to the surface of the sclera at the site of the tear or by a diathermy needle penetrating the sclera and choroid to reach the retina but not entering it. The interretinal fluid beneath the detachment is drained thoroughly either by penetrating diathermy needle punctures and suction or by trephining the sclera and puncturing the choroid, and secure choroido-retinal adhesions completely surrounding the tear are encouraged by placing the patient's head so that the retinal tear and the drainage puncture lie in the most dependent position obtainable. The effects of gravity of the vitreous assist this.

FIG. 1

The following statistics concern 78 officers and men of the Middle East Force suffering from retinal detachment and admitted to a military hospital in Egypt for investigation and treatment of this disorder from 1941 to 1943. Seventy-six were operated on; for one case surgical treatment was not advised, and another made a spontaneous recovery.

The operation performed in these cases was a combination of surface diathermy (90 to 100 mA for 8 seconds) placed around the edges of a tear or tears and penetrating diathermy;

one, two, and very rarely more punctures were made in the sclera with the diathermy needle carrying a current of 40 mA for 1 second (see Fig. 1). The interretinal fluid was sucked into a glass tube and rubber suction bulb applied to the sclera over the diathermy penetration. The patients were soldiers in good health between the ages of 20 and 47, the majority being in the third decade of life. This survey differs from a survey of retinal detachment in civil practice in two respects: (1) the incidence of myopia in retinal detachment would be appreciably higher than 3 in 78 cases; and (2) in civil practice injuries peculiar to war are of course not present. In the last the prognosis is adversely affected by the severity of the intraocular damage caused by blast and the ravages of high-velocity metallic missiles with ragged edges and rough surfaces.

I have classified the 78 cases as follows:

(1) Cystic degeneration	13
(2) Choroido-retinal degeneration	21
(3) Myopia	3
(4) Trauma (civil)	23
(5) Trauma (military)	18

Of these, 11 were officers—one a nursing officer (Q.A.I.M.N.S.). The remainder were other ranks, and included: Royal Navy, 2 cases; Royal Air Force, 2 cases; Royal Canadian Air Force, 1 case; and the Merchant Navy, 1 case. The following table shows the age incidence in decades in these five groups.

TABLE I.—Age Incidence

Age (Years)	Cystic Degeneration	Choroido-retinal Degeneration	Myopia	Trauma, Civil	Trauma, Military
20-30	9	16		18	15
31-40	4	3	2	5	3
41-47		2	1		

The nationalities were: British, 60; Canadian, 2; New Zealand, 1; South African, 3; Indian, 3; Greek, 4; Polish, 2; Czech, 1; German, 1; Italian, 1.

1. Cystic Degeneration (13 Cases)

The date of origin of the detachment was unknown in 11 cases. In these the condition was discovered in the course of routine examination. In two cases a sudden spread of the detachment from the limits of the cystic area caused separation of the macula so that the soldier noticed the visual defect. One sought advice one week after this event and the other four months later.

The position of the cystic area was peripheral in all cases. In 10 it was in the lower temporal quadrant, and in two of these it had spread to strip off the macula; in 2 cases the upper and lower temporal quadrants were affected at the periphery, and in 1 case the lower temporal and lower nasal quadrants were involved. In 9 cases there was a well-defined arc of pigmentary disturbance in the choroid and retina at the posterior periphery of the cyst up to the ora serrata, where these changes ceased. In 3 others this was faint. The ophthalmoscopic appearance suggested a line of adhesion between the retina and choroid, which was more marked in some cases than in others. In one case these changes were present in only part of the arc at the posterior periphery of the cyst.

In one case of haemangiogliomatosis retinae a retinal cyst was at the periphery of the lower temporal quadrant, remote from the neoplasm, which was behind the equator along the course of the

showed subacute inflammatory infiltration of the sinusoids, and the kidney post mortem degeneration. The lungs showed congestion and patchy collapse.

The one obvious comment on this case is that laparotomy was delayed too long, but the history and the physical signs on the right side led to a misdiagnosis. Why this spleen ruptured is difficult to determine and lends itself only to speculation. Though trauma is impossible to exclude, the husband was closely questioned and no history of trauma was forthcoming. From the pathological report this was not a strictly normal spleen, but no primary focus of infection was found—I am, etc.

Lambeth Hospital S.E. 11

R. I. HENDILASS

Service Medicine

SIR—Capt Piper's letter (Sept. 2) paints a very inaccurate picture of the life and work of a regimental medical officer. I was in general practice for some three years before becoming an R.M.O. of a gunner unit in 1940. I have remained with the unit in that capacity ever since. During two and a half years in the U.K. I was able to get to know the officers and men, their strong points and weaknesses without any difficulty whatsoever. The suggestion that mistrust is engendered by an R.M.O.'s 'friendliness' with his C.O. is an extraordinary one. It presupposes that the men have no trust in or respect for the average C.O. that he is in effect an ogre and completely inhuman. Nothing could be further from the truth.

I found the job of weeding out those men whom I considered to be unfit mentally or physically for active service overseas, and helping to promote and maintain the health of the remainder, both novel and stimulating. For the first time in my life I was able to appreciate the importance of preventive medicine, and had time to think over the elemental reasons for sickness and to realize the major part played by environment, living conditions, nutrition, etc.

The statement that 'any sick must immediately be sent to hospital as the equipment provided lacks the essential for diagnosis' is grossly exaggerated. Every R.M.O. has an auriscope and I have never been handicapped by the lack of a sphygmomanometer, having for the most part to deal with constitutionally fit men between the ages of 20 and 40. Admittedly I have no microscope, but here I should like to digress a moment. In the alternatives that Capt Piper offers for a G.P. in the Army he makes no mention of field ambulances or dressing stations. It is possible that he includes these in the term 'collecting units', but it so he is doing them an injustice. When not functioning on an active front these units hold and treat a large number of sick. These are cared for by M.O.s without clinical interference from their C.O. They have access to a microscope which they can and do use.

Diagnosis remains the crux of medicine, and cases have to be sent to hospital for investigation even in civilian practice. My only regret is that I have not had the opportunity to practise obstetrics or administer anaesthetics—I am, etc.

J. A. J. HAMMOND,
Capt R.A.M.C.

SIR—Under Thirty is clearly but recently commissioned. If he had had more experience of medical practice before joining whatever Service he now belongs to he would have understood better what is required of a doctor, either in a Service or out of it, for the good of his patients.

In many branches of the fighting Services, and particularly in the medical branch, the number of forms to be completed is certainly large and the work involved is considerable and tedious. But, although many attempts have been made to effect a reduction, it has proved impossible to do so without impairing efficient administration or the clinical records which are so essential to the ultimate welfare of the individual patient and his comrades still actively engaged in war. Let "Under Thirty" try to understand the purpose of each of the returns which he has to render, and then decide if any one of them can be eliminated. And when he has had longer service he will probably better understand the responsibilities which make it necessary that every officer should inspect and be answerable for the equipment of troops in his charge.

Having myself just completed a long period of active service in the Army there is one remark in his letter which I consider should not be passed without comment, for it is a gross misrepresentation of the spirit both of the troops and of the doctors who look after them, and I do not doubt that it has no fairer application to either the Navy or the R.A.F. He says, speaking of sick parades: "One thinks not of a patient to be healed but of a man who may be trying to get away with something (not a malingerer, for they are rare, but an exaggerator) and he has to prove he is ill before you start to think of him." It is most sincerely to be hoped that

Under Thirty is serving in some large medical unit and is therefore under the immediate command of a senior officer. For if he were on his own—for example, M.O. to a battalion—his attitude at sick parade might well prove disastrous until the C.O. quite realized what was going wrong.

But Under Thirty "need not despair." When he returns to civil life he will learn, in whatever form of practice he may follow, that the great proportion of his patients who exaggerate are not "trying to get away with something" but truly need his advice. Fortunately, most Service M.O.s realize this, give their advice gladly, and thereby do much to maintain the fighting efficiency of the troops—I am, etc.

London W. 1

R. OGIER WARD

Obituary

SIR JAMES DUNDAS GRANT, K.B.E.,
M.D., F.R.C.S.

One of the best known names in British otology and laryngology has passed into history with the death of Sir James Dundas-Grant on Nov. 13. It is astonishing over how long a period his career extended. He had already been in general practice for ten years when he took up his specialty in 1886, and more than fifty years later he was still a prominent figure at all assemblies of ear, nose, and throat surgeons. Though he had long retired from practice, and his vitality in recent years had been diminished as a result of a street accident, he would examine clinical cases or specimens with the eagerness of youth and join in the discussions, recalling details of like cases he had seen or surgical procedures he had followed at any time within the last half century.

James Dundas Grant was born in Edinburgh in 1854, the son of a Scottish advocate. He received his education at Edinburgh Academy and went to Dunkirk College, France, as a finishing school. He then entered Edinburgh University, where he took his M.A. in 1873, spent some time also at the University of Würzburg in Bavaria and afterwards came to London, where he completed his medical studies at St. Bartholomew's. He qualified in 1876, took the Edinburgh M.D. with honours in 1879, became Fellow of the Royal College of Surgeons of Edinburgh in 1884, and Fellow of the English College, by examination, in 1890. In 1879 he was appointed surgeon to the Central London Throat and Ear Hospital, an appointment he continued to hold until 1913, when, retiring under the age limit, he became consulting surgeon, and so remained for many years. No doubt it was his association with the institution in Gray's Inn Road that determined him eventually to confine his work to otology and laryngology (he would never have it that there were two separate specialties). He also held appointments at various other hospitals—Brompton Hospital for Consumption, where he continued to be consulting surgeon to the ear and throat department for many years after his retirement, the Cancer Hospital, the West End Hospital for Diseases of the Nervous System, the Freemasons' Hospital at Hammersmith, and the Sussex Throat and Ear Hospital at Brighton. He was an excellent and intimate instructor with the University of London. His pen also was extremely active. It does not appear that he ever wrote a book, but he was a prolific contributor to the medical journals, general and special, and to the annuals and encyclopaedias, on the subject of the ear and throat. He had an inquiring mind, an aptitude for precise detail, and a good deal of mechanical ingenuity. Again and again at medical meetings he would bring forward some new contrivance—or more often perhaps some old contrivance of his own devising such as a cannula for aspirating the middle ear, or a ligature applicator for tonsillar and other deeply seated vessels, or some modification of an aid for hearing so as to make it more efficient or comfortable. He rarely lost an opportunity to intervene in debate, and generally it was to contribute something from his own experience.

upper temporal vessels. There were no apparent degenerative and pigmentary changes in the retina and choroid at the edge of the cyst.

A retinal tear or tears were found in 12 cases; in the remaining one, which was associated with haemangiogliomatosus retinae, there was no tear. The retinal tears were at the ora serrata in 9 cases, in five of which a single tear was present; in 2 there were two tears, in 1 there were two tears at the ora serrata and two posterior to this, in another case four at the ora serrata and three posterior to this. In one case the tear was a single round hole about 1.5 mm. behind the ora serrata. In two instances no clearly defined hole was evident; in one of these there were two thin areas of atrophic retina and in another four such areas, two of which were minute. These were all placed about 1.5 to 2 mm. behind the ora serrata.

The right eye was affected in 9 and the left in 4 cases. The intraocular pressure was 1 to 2 mm. Hg below normal in 3 cases, in 1 it was 2 mm. Hg above that in the other (normal) eye, and in the remainder it was equal in both eyes. One month after operation it was 6 mm. Hg, often less, and it gradually returned to normal in 3 to 6 months after operation.

One operation in each case successfully replaced the retina, sealed the tear, and restored the visual field. There were no failures. This type of case is particularly favourable for surgical treatment. The danger of a sudden spread of the detachment justifies an operation in which the chances of success are, it seems, 100%.

The change in refraction from before to after operation was too slight to be of any significance. Between 3 and 6 applications of surface diathermy were made to the sclera, and the difference of 0.5 to 1 D of astigmatism and the change of axis up to 30° may have been due to subsequent contracture of the sclera at the diathermy sites and the effect of this on the cornea. The change in refraction was not constant until the intraocular pressure was re-established.

Visual Result—In 11 cases the visual acuity was 6/9, 6/6, and 6/5, and it remained unchanged after operation. The two patients in whom the macula was detached improved to 6/24 (1 letter).

2. Choroido-retinal Degeneration (21 Cases)

Retinal detachment in this group was associated with areas of choroido-retinal scarring and degeneration. In many instances multiple small holes were present in the thin degenerate area of the retina. The duration of the detachment, so far as could be ascertained from the patients' history, was as follows: 2 to 8 weeks, 9 cases; 4 to 12 months, 4 cases; 2 years, 1 case; 5 years, 1 case; 6 years, 1 case; 8 years, 1 case; 13 years, 1 case; 17 years, 1 case; and unknown in 2 cases. The area of detached retina was: upper and lower temporal quadrants and lower nasal quadrant in 7 cases; the lower temporal and lower nasal quadrants in 9 cases; the lower temporal quadrant in 3 cases; the upper temporal quadrant in 1 case; and the upper nasal quadrant in 1 case.

The tears in the retina were single in 10 cases, and these were all placed at the ora serrata. Two holes were present in 3 cases; in two these were in the upper temporal quadrant and in one at the ora serrata. In one case there were three holes on the temporal side, and in another four holes at and near the ora serrata in the lower temporal quadrant. In 4 cases many minute holes were present in an area of choroido-retinal atrophy in the upper temporal quadrant in each instance. In 2 cases there were very thin atrophic areas of retina in the lower temporal quadrant at and posterior to the ora serrata, but no definite hole was evident.

The right eye was affected in 11 cases and the left in 10. The intraocular pressure was 0.75–2.25 mm. Hg below that in the other normal eye in 4 cases; it was 3.75 mm. Hg higher than the normal

eye in 1 case and 2.25 mm. Hg higher in another. In the remainder the intraocular pressure was equal in both eyes. In all cases the retina was replaced and the visual field restored.

Visual Result and Refraction.—In 18 cases in this group macula was detached. Two of these recovered 6/12, two 6/18, 6/24, and the remainder 6/36 to 6/60. The 6/60 was obtained eccentrically by a few. Two patients had visual acuity of 6/5 and one 6/6. In 4 cases astigmatism of 1.25 D—two myopic and two hypermetropic—was present after operation.

3. Myopia (3 Cases)

The degree of myopia was 8 D in one case, 5.5 D with 2.5 D astigmatism in another, and 3.75 D in the third. The duration of the detachment was two to three weeks in all cases. The area of detachment was in the upper temporal quadrant in 1 case, the upper temporal and upper nasal quadrants in 1 case, and the upper and lower nasal quadrants in 1 other.

Retinal Tears.—In one case there were seven tears between the equator and the ora serrata in the upper temporal quadrant. Two of these were crescent-shaped and larger than the others, which were ragged and irregular. The line of tears in this case was continuous with a zone of choroido-retinal degeneration about 2 mm. wide in the lower temporal quadrant. In another case there was a single arrowhead-shaped split at the ora serrata in the upper temporal quadrant in the 11.30 o'clock meridian. Also in this case there were two linear areas of atrophic retina in the 11 o'clock meridian between the equator and the ora serrata. In the third case there were three holes just in front of the equator in the upper nasal quadrant. One of these was in the 3 o'clock meridian, 4.5 mm. in length and kidney-shaped. Another, about 2 mm. in length, was crescent-shaped in the 2 o'clock meridian, and close above it was the third hole, which was round and about 0.25 mm. in diameter.

The intraocular pressure behaved similarly to that in the other groups of retinal detachment. In the eye with the retinal detachment it was 1 to 2 mm. Hg below the other eye. One month after operation it was less than 6 mm. Hg in

2 cases and 6 mm. Hg in 1 case. In three months it had risen to 8.75–10 mm. Hg.

Two cases were successfully treated by operation. The third had a vitreous haemorrhage on the fourteenth day, and subsequently a shallow localized retinal detachment associated with a fold in the retina appeared in the upper nasal quadrant.

Visual Result.—In the two cases with the retinal detachment in the upper temporal quadrant the macula was detached and visual acuity was less than 6/60 before operation. One of these, a myope with 8.25 D, recovered 6/36; the other, with 2.75 D of myopia, had 6/9 (4 letters) after operation. The recovery of the visual field was complete in the latter case and apparently so in the former, although indeed the physiological conformation of the lower nasal field must have masked the peripheral scotoma resulting from the applications of diathermy to the upper temporal quadrant. In the third case, in which a retinal fold recurred in the upper nasal quadrant, the visual field was substantially improved by operation.

4. Civil Trauma (23 Cases)

In these cases the cause of the detachment was a blow from a blunt object or a severe contusion around the eye—e.g., in boxing and football, from a door handle, the corner of a bed-post, a "kenneke" stick, a fall from a motor vehicle, and the explosion of a battery accumulator. The duration of the detachment was unknown in 1 case, 9 to 21 days in 5, 1 to 9 months in 8, 1 year in 2, 3 years and 5 months in 1, 5 years in 1, 6 years in 2, 8 years in 1, 10 years in 1, and 27 years in 1.

LEGENDS FOR FIGURES

FIG. 1.—Retinal detachment operation. Exposure of the sclera at the site of a retinal tear in the upper temporal quadrant of the left eye. The flap of conjunctiva and Tenon's capsule is held reflected by two sutures. Two traction sutures pass through the tendon of the adjacent recti muscles. Surface diathermy has been applied to the sclera and penetrating diathermy is being made at the posterior edge of the tear about the equator.

FIG. 2.—Drawing of left fundus of Dvr. H. E. Intraocular contracting scar tissue on nasal side from 6.30 to 10 o'clock. In the 3 o'clock meridian there is a dense fibrous band which runs posteriorly behind the equator. The retina is detached above and below this band.

FIG. 3.—Dvr. H. E. Diagram of operation. The internal rectus is divided. The small shaded circles represent the sites of surface diathermy applications, and those with the dark point in the centre are the positions of penetrating diathermy. Two sutures retract the posterior edge of the conjunctival incision. Two mattress sutures have been passed through the external rectus muscle, and one is acting as a traction suture in the tendinous insertion of the muscle. The scleral wound is exposed.

FIG. 4.—Fundus drawing of right eye of Soldat R. K. (German Army). Dense white contracting fibrous tissue from 4.30 to 7.30 o'clock. A sheet of this fibrous tissue extends posteriorly to a point between the equator and the optic disk. In this band is a mass of proliferated choroid which resembles a foreign body. The lower half of the retina is detached. Just below the optic disk there are some vertical retinal folds and a transverse arc of pigment deposits. In the upper nasal quadrant above the upper level of the retinal detachment and near the optic disk are two choroidal splits. On the surface of the retina in the lower nasal quadrant are some interlacing bundles of fibrous tissue.

A joint meeting of the Scientific and Technical Group of the Royal Photographic Society and of the Association for Scientific Photography to discuss electron microscopy will be held to-day (Saturday, Nov. 25) at 3 p.m., at the rooms of the Royal Photographic Society, 16, Prince's Gate, London, S.W.

A lecture on research in all its various aspects essential for the promotion of health and the prevention of disease (arranged by the Chadwick Trustees under the Malcolm Morris Memorial Trust) will be given by Dr. J. A. H. Brincker on Tuesday, Nov. 28, at 2.30 p.m., at Westminster Hospital Medical School, 17, Horseferry Road, S.W.

Mr. Somerville Hastings, chairman of the L.C.C., will deliver an address on "Hospitals in a New World" to a meeting of the Polish Medical Association in the United Kingdom on Tuesday, Nov. 28, at 5 p.m., in the Hastings Hall of B.M.A. House. Medical practitioners and medical auxiliaries will be welcome.

Brig. L. E. H. Whitby will give a lecture on the Army Blood Transfusion Service, illustrated by lantern slides, at the Royal Society of Arts, John Adam Street, Adelphi, W.C. on Wednesday next, Nov. 29, at 1.45 p.m.

The Scientific Film Association is presenting a programme of recent films of medical interest, chosen by its Medical Standing Committee, by invitation of the Royal Society of Medicine, at 1, Wimpole Street, W.1, at 5.30 promptly, on Thursday, Dec. 7. The meeting is open to medical practitioners, medical students, and nurses in the London area, but by ticket only, to be obtained from the Medical Hon. Secretary, 14, Hopton Road, S.W. 16, before Dec. 1.

The Council of the Royal Medical Foundation of Epsom College will shortly proceed to award St. Anne's Scholarships to girls attending Church of England schools. Candidates must be fully 9 and under 16 years of age, and must be orphan daughters of medical men who have been in independent practice in England or Wales for not less than five years. The Council will also in March award a "France" pension of at least £30 per annum to a necessitous medical man, fully 55 years of age, who has been registered for five years. Forms of application for the scholarships and for the pension can be obtained from the Secretary's Office, Epsom College, Epsom, Surrey, and must be completed and returned to that office by Jan. 15, 1945.

The Ministry of Health has issued to County Councils, County Boroughs Councils, and Joint Cancer Committees a circular (123/44) enclosing printed directions for the use of record cards for cancer cases which the Minister has prescribed after detailed consultation with the Cancer Subcommittee of his Medical Advisory Committee.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week measles, diphtheria, and whooping-cough rose in incidence by 385, 79, and 74 cases respectively, while falls were recorded for scarlet fever 139, and dysentery 106.

Yorks West Riding recorded a rise of 188 in the incidence of measles. There were also rises in Cheshire and Warwickshire of 101 and 96 respectively, but a fall of 116 in Lancashire, where, nevertheless, one-third of the notifications for the country were reported. Cheshire had 31 more cases of whooping-cough than last week. The great increase in diphtheria resulted in the largest weekly total for over six months. Lancashire had 48 more cases than last week (Lancaster M.B. 24 more), and Cheshire 28. The fall in scarlet fever ends a continuous rise of ten weeks; Nottinghamshire had 45 fewer cases than last week, and Yorks West Riding 42.

Although the notifications of dysentery fell by 106 to the lowest level of the past eleven weeks, the incidence is still high, 256 cases being recorded. The largest returns during the week were London 38, Surrey 33, Essex 31, Lancashire 30, Glamorganshire 22, Gloucestershire 11, Yorks North Riding 11. During the past eleven weeks 35% of the total notifications were recorded in the region comprising London, Surrey, Kent, Middlesex, Hertfordshire, and Essex.

In Scotland the only notable fluctuations in the incidence of infectious diseases were an increase of 34 for scarlet fever, and a decrease of 35 for diphtheria.

In Eire the incidence of infectious diseases underwent little change. One case of typhus fever was reported from Galway, Loughrea R.D.

In Northern Ireland the notifications of measles in Belfast C.B. rose from 96 to 143.

Week Ending November 11

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,132, whooping-cough 1,297, diphtheria 642, measles 5,752, acute pneumonia 583, cerebrospinal fever 37, dysentery 320, paratyphoid 3, typhoid 4, acute poliomyelitis 13.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 4.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

Live births Annual rate per 1,000 persons living	6,653	545	896	320	274	5,675	717	839	336	263
Stillbirths Rate per 1,000 total births (including stillborn)	228	19	39	—	—	189	22	42	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

The Area of Retinal Detachment—The retina was totally detached in 2 cases—one a Greek and the other an Italian—and in both here was a large tear at the ora serrata in the upper nasal quadrant. In the latter the retina was cobbled up in a mass of scar tissue, an organized haemorrhage in the course of the superior temporal branches of the central retinal vessels about 4.5 mm from the optic disk. The former showed opacities in the upper nasal quadrant of the lens. The detachment was present in the upper temporal, lower temporal, and lower nasal quadrants in 10 cases, the upper and lower temporal quadrants in 2, the lower temporal quadrant in 2, the upper temporal quadrant in 1, the upper temporal and upper nasal quadrants in 1, the upper temporal and upper and lower nasal quadrants in 1, the upper and lower nasal quadrants in 1, the upper and lower nasal and lower temporal quadrants in 1, the lower temporal, upper nasal, and lower nasal quadrants in 1, and the lower nasal quadrants in 1.

Retinal Tears—The tear in the retina was single in 18 cases. In 10 it was at the ora serrata in the lower temporal quadrant, and in three of these the tear extended into the lower nasal quadrant. A tear at the ora serrata in the upper nasal quadrant was present in 2 cases and in the lower nasal quadrant in 1 case. A long elliptical tear, with its long axis horizontally, ran across the equator of the upper nasal quadrant in 1 case and was accompanied by a vitreous and retinal haemorrhage. In another case a large rent at the ora serrata extended into both the upper and lower temporal quadrants. A round hole was present between the equator and the ora serrata in the 9 o'clock meridian on the temporal side in one case. A large crescent shaped tear occupied most of the upper temporal quadrant between the equator and the ora serrata in one case. In one case there was a round hole in the upper nasal quadrant between the equator and ora serrata. In the 5 multiple cases the number and disposition of these tears were as follows: upper temporal quadrant, five tears between the equator and ora serrata, one of which was arrowhead shaped and the other four smaller and irregular; lower temporal quadrant at the ora serrata, two tears in one case, in another case between the ora serrata and the equator six tears, one of which was crescentic and the other five smaller than this and irregular; lower temporal and lower nasal quadrants, two tears—one at the ora serrata and the other a round hole about 1 mm posterior to it. In the fifth case two large rents each ran obliquely across the equator and along the course of the upper temporal and the lower nasal branches of the central retinal vessels respectively. The upper temporal tear was the larger, and extended to within 1 mm of the optic disk.

The right eye was affected in 9 cases and the left in 14. The result of operation was successful in 20 cases. Of the three failures, two were cases of total retinal detachment—the Greek and the Italian described above. In the case of the Italian there was little chance of success on account of the cobbling together of the retina in a mass of organized blood-clot. At the best we hoped to give him some slight improvement of visual field. The failure of the Greek to co-operate in post-operative postural rest may or may not have been responsible for failure in this serious case. In the third case two large rents were present, one extended from in front of the equator to within 1.5 mm of the edge of the optic disk along the upper temporal vessels, and the other was long but less extensive along the course of the lower nasal vessels. The retina was detached in the nasal half of the fundus and part of the upper temporal quadrant. The retina remained in place for 25 days after operation and then the detachment recurred in the lower nasal quadrant.

Visual Result, Visual Field and Refraction—In 4 cases vision improved from 6/60 to 6/9, 6/60 to 6/12 (4 letters), 6/12 to 6/6, and 6/6 to 6/5. In 7 cases it remained the same, in three of these it was 6/5, in one 6/6, in one 6/12, and in two others 6/36. In 9 cases the macula was detached, and in all these the vision was less than 6/60. It improved to 6/9 in one case and 6/60 in eight. In the three failures it remained 'hand movements' in two cases and was 6/60 in the other. The visual field was improved in all the successful cases. The alterations in refraction were small in the majority and amounted to the appearance of +0.5 D and -0.75 D astigmatism, with axis variations of 15° from before operation. In two instances when seven and nine applications of surface diathermy had been made respectively at the ora serrata in the lower temporal quadrant it seemed that subsequent contraction of the sclera produced two months after operation an increase of corneal curvature opposite the site of application, so that -1.75 and -2.25 cylinders set at an oblique axis (20-30°) were necessary to correct this.

5. Military Trauma (18 Cases)

The area of retinal detachment was extensive in a number of these cases. Large splashes of blood on the retina, in the choroid and vitreous, exudates, subsequent fibrous organization of intraocular blood, the presence of blood between the retina and the choroid, and the lowered intraocular pressure as the result of severe concussion of the eye from blast were factors against successful treatment. It is probable that vitreous gel passes through some of the large ragged

rents in the retina and is a mechanical factor in preventing choroido-retinal adhesions from forming after diathermy.

In one case in this series of 18 the intraocular changes were such that surgical operation seemed to hold out no hope of effecting any improvement. The soldier had sustained a blast injury from an aerial bomb which exploded 200 yards to his right front. Three months after the injury the retina was totally detached, dense white broad sheets of organized blood clot were adherent to it in the lower half of the eye, over the macula, in the upper nasal quadrant, and in front of the equator above. The inferior branches of the central retinal vessels immediately below the optic disk were kinked and tortuous. There was much pigmentary disturbance in the retina and the intraocular pressure was 65 mm Hg. Vitreous had herniated forwards into a coloboma of the iris in the lower temporal quadrant, the suspensory ligament having been ruptured at this site.

Spontaneous recovery of retinal detachment in the upper temporal quadrant occurred in an officer who was wounded by a fragment of shell which struck the temporal end of his left supraorbital margin. There were a severe contusion of the left eye and a rupture of the choroid at the macula, and large splashes of blood and exudate were present on the retina and in the choroid and vitreous of the upper temporal quadrant. One month after this wound the retina in the upper temporal quadrant became detached. There was no hole evident. The intraocular pressure was 6 mm Hg and visual acuity less than 6/60. Postural treatment was tried for three and a half weeks. The detached area became slightly smaller and some of the interretinal fluid was absorbed. Within two months of the onset of the detachment the retina was completely restored to its normal place.

In this group of 18 cases 3 had lost one eye (the left in each case), which was destroyed beyond hope of repair at the time of wounding. In 8 cases the right was affected, and in 10 the retina was detached in the left eye. In most the actual duration of the retinal detachment was difficult to assess accurately. In some instances it was apparent a few days after wounding, in others it was obscured by intraocular haemorrhage and did not become evident for several weeks, while in a few it occurred as a late sequel, 6 to 14 months after the injury. In the latter the contraction of fibrous tissue attached to the retina and the lowered intraocular pressure were likely causes. The times, taken from the date of wounding, were 1 to 11 days 6 cases, 1 to 4 months, 8 cases, 4 to 6 months, 3 cases, and 14 months, 1 case.

Retinal detachment occurred in association with an intraocular foreign body in 5 cases. The detachment happened immediately in one case, 53 days later in another, and in a third 6 weeks after the extraction of an intraocular foreign body, at another hospital, by the posterior route, in which diathermy was not used at the site of sclerotomy. In the other 2 cases the date of onset of the detachment was not known. Of the intraocular foreign bodies, three were extracted by the magnet through the posterior (scleral) route, one was removed by a snare and forceps guided under ophthalmoscopic view, and another was too small and non magnetic, and so was left.

In 3 cases tangential cuts in the sclera were caused by a shell fragment, which did not remain in the eye but passed on into the orbital tissues. Blast from a shell and an aerial bomb caused retinal detachment in 3 cases, hand grenades were responsible for 2, land mines for 2, a rifle-butt for 1, a bullet traversing the orbit for 1, and a fragment of mortar bomb for 1.

The site of the retinal detachment was total in 2 cases, almost total in 2, involved the lower half of the retina in 4, the upper and lower temporal quadrants in 2, the upper and lower temporal quadrants and lower nasal quadrant in 4, the upper and lower nasal quadrants and the lower temporal quadrant in 2, the upper temporal quadrant in 1, and a curtain like detachment affecting the upper nasal and upper temporal quadrants and the lower nasal and lower temporal quadrants in 1 (see Fig 2). There was no hole present in this case. Fig 3 is a diagram of the operation. The internal rectus muscle was divided temporarily at its insertion in front of two mattress sutures. Beneath the muscle belly was seen a tangential wound in the sclera just in front of the equator in the 9 o'clock meridian. The wound was linear, 3 mm long, vertical, and, gaping, it revealed the choroid. The application of surface diathermy on either side of it closed it by contracting the sclera. A line of surface diathermy applications was made at the equator between the nasal borders of the superior and inferior rectus muscles. From the upper and lower ends of this line applications of diathermy were made forwards to the ora serrata. Thus a frame was made just clear of the scar tissue inside the eye and with the object of pinning down the retina. The interretinal fluid was drained by penetrating diathermy at two points—one at the equator just above the upper margin of the internal rectus and the other at the equator in the lower nasal quadrant.

A retinal tear was present in 5 cases, in one of these there were three tears and in another two tears. In two of these cases the retina was torn by the passage of the foreign body through it. In

Treatment of Varicose Ulcer

Q.—A man aged 65 has had an ulcer on the medial side of the lower third of the leg for four years. When I saw him first it extended half-way up his leg. I injected his veins with ethamolin and they are now normal. W.R. negative. He has had elastoplast and viscopaste bandages, but now he cannot tolerate either of these or ichthopaste. Despite many treatments with rest the ulcer remains indolent.

A.—First, the presence of diabetes, local or general nerve disease, obliterative arteritis, and syphilis should be excluded. In addition, active absorption from septic or dead teeth and infected tonsils will prevent an ulcer from healing. The diabetes is occasionally latent by the patient having a high renal threshold; recently a case was seen where it was 280, only a complete diabetic investigation revealed it. The ulcer, which had been under treatment on and off for four years, healed in less than a fortnight when dieting and insulin were started. The obliterative arteritis is detected by the absence of pulsation in the dorsalis pedis artery and when it is caldified, by x-ray examination of the leg.

The local conditions are the persistence of varicose veins. There are two types, although rare and not generally known which may be present. The first is incompetence of the external saphenous vein, which can be detected by the two tourniquet test—i.e., elevating and emptying the veins, putting on two tourniquets, one above and the other below the knee, and asking the patient to stand. The lower band is then released, and if the external popliteal vein is incompetent a down filling wave of varicose size will be seen in the veins of the leg. The second item is inefficient deep communicating veins, usually situated in the lower third of the inner surface of the leg and diagnosed by feeling a defect in the deep fascia somewhat like a button-hole. There may be one or two such vessels. They are not easily detected. Another way to prove their presence is to put on a tourniquet below the knee, ask the patient to stand, and if the communicating veins are faulty the empty veins will be seen to fill up within thirty seconds.

The treatment is to ligature and inject the external saphenous vein at its termination in the popliteal space. The communicating veins are cut down on and dissected out, divided between ligatures, and the deep fascia closed. The bleeding from them is surprising in its volume and pressure. The operation is more difficult than ligatures and injection of either the internal or external saphenous veins, but the results in these persistent ulcers make the trouble worth while.

Synovial-tissue Proliferation

Q.—Is the operation of bilateral removal of patellae likely to be worth while in treatment of serious synovial-tissue proliferation with much grating on knee movement and pain in rubbing the patellae against femoral condyles?

A.—The operation of bilateral removal of the patellae for the relief of serious synovial tissue proliferation with much grating on knee movement and pain would appear to be a heroic remedy which might easily increase the disability it was sought to relieve, simple synovectomy, which has been practised especially in America, would be a more appropriate procedure.

Human Semen by Post

Q.—Artificial insemination of human semen is, I believe, increasingly practised in America. Can you tell me what is the ideal temperature for keeping semen and, if sent by post, how long it will remain active?

A.—Semen for artificial insemination should be as fresh as possible (not older than 3 hours). It should be collected without a sheath into a warm glass tube. Sudden chilling seriously disturbs the viability of some specimens. If the semen is going to be used within 2 hours of collection it is probably best to keep it warm (near to blood heat). If the interval between collection and insemination is going to be longer (2 to 6 hours) it is best to allow the specimen to cool gradually to cool-room temperature (about 25°C) and to inseminate at this temperature; contact with the female and genital tract will do all the warming up that is needed. It is not desirable to delay longer, as the chances of success, even with highly fertile specimens, are then much reduced. It is extremely unlikely that a specimen of human semen sent by post (12 to 36 hours old) would still be capable of effecting fertilization, but perhaps they would find speedier postal services in America than we have here in war-time. The only chance of preserving fertilizing capacity for 12 hours or more would be to dilute one part of semen (provided it had an initial density of at least 100 million per c.c.m.) with 2 or 3 parts of Walton's buffered glucose or egg-yolk-citrate solution, cool it gradually to 4°C, and post it in a thermos packed with ice. The writer has no first-hand experience of this method, and feels it would be simpler to get the donor to transport himself nearer to the recipient.

Staphylococcal Infection of Bone

Q.—How long can a staphylococcal infection of bone remain latent or quiescent? Can an osteomyelitis of lower end of femur, which eventually necessitated amputation, be attributed to a compound fracture of lower end of same femur which happened 25 years ago? There was no history of any recent accident but the patient had a meningococcal meningitis about a year previously.

A.—That staphylococcal or other infection of bone may remain latent for many years is well known, and it would be rash to put any limit to its latency. It is unusual for the organism to remain quiescent and alive in bone for many years without giving some indication of its presence. C. W. Pannett (*Surgery: A Textbook for Students*, Hoddar and Stoughton) writes of osteomyelitis of bone on p. 462. The organism which is responsible appears to acquire a predilection for growing in bony tissue, and it also appears to be capable of remaining quiescent for a very long time, often many years so that in subsequent life it may be responsible for inflammation of the bone in its neighbourhood, or attack another bone. While it would certainly be possible to attribute an osteomyelitis of the femur to a latent infection incurred at the same site twenty-five years earlier it would nevertheless be unreasonable to do this in the complete absence of symptoms referable to that site during the whole of that period.

Eczema-Prurigo-Asthma Syndrome

Q.—Can you advise me as to treatment of a chronic irritation of skin of face, neck, front of chest and arms in a girl of 18 who has had infantile eczema when she was 6 months old which left her with eczema on and off till she was 9 years old? Her asthma now only comes on when she has a bad attack of cold but lately (last 18 months) she is troubled with skin irritation which does not respond to any treatment—lotions or ointments. She is healthy and well developed in all respects and has a varied diet. Rash at times looks urticarial at other times it resembles a bright-red inflammation—very rarely weeps. Face at times gets puffy and she has difficulty in opening her eyes in the morning.

A.—The girl described is suffering from what is usually known as the eczema-prurigo-asthma syndrome if the skin irritation is predominantly round the neck and in the flexures of the elbow and wrists. In addition she appears to get some urticaria, and the swelling of the eyelids and face in the morning is an angioneurotic oedema. These are allergic conditions, due in early childhood largely to foods but after puberty more often due to a sensitivity to feathers, dusts, powders, animal hairs, pollens, and even drugs, and the patient should be skin-tested intradermally with such irritants. Failing this the pillows, bolster, mattress, and eiderdown should be freed from any feathers, down, horsehair, or dusty substances such as old kapok or flock, orns-root face or talcum powders be forbidden, and animals be removed from the environment. If dust or pollen sensitivities are suggested or shown on testing, desensitization is necessary. Most of these cases show a diminished secretion of hydrochloric acid in the stomach, so 20 minims before each meal in a glass of water would be beneficial. To cut down the irritation, ephedrine hydrochloride (1/2 gr) and luminal (1/2 gr) each morning and evening would be helpful. If the general skin is very dry, thyroid therapy leads to improvement. The puffiness of the face on waking is due to a sensitivity to a feather, down, or horsehair pillow or to an aspirin or veganin tablet taken at night or both. As many of these cases in early childhood are fish-sensitive, a synthetic vitamin preparation should replace halibut oil.

A Case of Myxoedema

Q.—Could you please give me advice on the following case? History: Patient aged 30 married, no children, operated on for toxic goitre August 1943. Subsequently developed what I took to be myxoedema with thickening of the subcutaneous tissues and complete loss of hair. I treated her with thyroid extract up to 6 grains daily. The hair came but has again suddenly fallen out, although she is still taking 6 grains of thyroid daily. The thyroid never had any effect on the general body swelling, and the pulse rate never went above 76. She also has amenorrhoea, for which I gave her stilboestrol, with no effect. Is there a possibility of pituitary involvement? The pupils are often widely dilated, sometimes she sees double and has headache. Urine normal, no sugar, B.P. normal. She will not consent to go into a hospital for treatment and investigation.

A.—This is a bit of a teaser. We can assume that the diagnosis of post-operative myxoedema was correct. It is a possibility (made probable by the fact that the body swelling was not reduced or the pulse rate greatly increased) that the dose of thyroid was insufficient. Much higher doses are sometimes required. The recent relapse suggests that even to the insufficient dosage she has developed some degree of tolerance. Amenorrhoea is a fairly common concomitant of myxoedema. The exact explanation is not known with certainty. One hypothesis relies on the fact that both the gonadotrophic and thyrotrophic hormones are secreted by the basophil cells of the

two instances the tear and detachment were the result of blast, and in a third these were caused by the contusion from a blow with the butt end of a rifle. In 2 cases there was doubt as to the presence of a minute tear. In the remaining 11 cases no tear was evident.

Vitreous.—There was prolapse of vitreous at the site of a penetrating wound in one case; a knuckle about 3 mm in diameter was lost. Some vitreous haemorrhage was present in 5 cases at the time of wounding, and in 1 case it occurred 9½ months after an operation for retinal detachment. A moderate vitreous haemorrhage was evident in 7 cases. The contracture of organized bands of fibrous tissue was a factor in producing the detachment in 9 cases. Fig. 4 shows, like Fig. 2, the result of contracture of fibrous tissue

6 failures, 3 were at first successful but later showed a recurrence localized to part of a quadrant of the fundus, the onset of this after operation being 6 weeks in one case, 5 months in another, and 8 months in the third case. The patient whose retinal detachment recurred 5 months after operation had for military reasons to be evacuated 18 days after operation, and the long journey from Egypt round the Cape of Good Hope to the United Kingdom may have been a factor in causing this misfortune. A spontaneous vitreous haemorrhage 8 months after operation was probably responsible for another case. In one case it was difficult to account for a shallow residual detachment in the lower part of the eye. This patient had an intra-ocular foreign body extracted by the giant electro-magnet and the

FIG. 2

FIG. 4

FIG. 3

bands in a contused eye. Fig. 3 is the fundus of the right and only eye of a German prisoner. He was wounded in the face with multiple shell fragments. The retina became detached 14 months after he was wounded. Operative treatment was successful in this case. A line of diathermy applications was made to the sclera beyond the limits of the scarred area, the interretinal fluid was drained, and the detached retina pinned down to the choroid. The retina remained in place.

Intraocular Pressure.—In 6 cases of severe contusion of the eye the intraocular pressure was reduced. In two of these with total detachment of the retina the intraocular pressure was less than 6 mm Hg in one case and 6.5 mm Hg in the other. In one case of severe contusion with retinal detachment on the temporal side the intraocular pressure was less than 6 mm Hg. In the 3 other cases it was from 1.25 to 9.5 mm Hg lower than that in the normal other eye. In 2 cases the intraocular pressure was higher in the eye with the retinal detachment than in the other (normal) eye. This amounted to 1.25 mm Hg in one case and 4 mm Hg in the other. After operation the recovery of the intraocular pressure was slower than in the other groups of this series. The normal was not reached until 10 to 11 months after operation, and in some instances the intraocular pressure remained 1.5 to 3 mm Hg below this.

Results of Operation.—Sixteen out of 18 cases in this group were operated on. In 10 the retina was completely replaced. Of the

detachment treated by diathermy. No definite hole was found in the retina, and despite the recurrence of the detachment his vision was 6/9 and the intraocular pressure within physiological limits. In another case a shallow detachment persisted in the lower part of the eye up to two months after operation, when the patient was last seen. Vitreous bands were probably the cause. In the sixth case the operation failed to seal off a large rent at the ora serrata which occupied most of the lower temporal quadrant and to secure replacement of over half of the retina. A further operation is necessary in this case.

Vision. Visual Field. Refraction.—Vision improved after operation in 6 cases. In one it was 6/36 before operation and was reduced to counting fingers at 1 ft. as a result of a late vitreous haemorrhage 9½ months after operation. In the remaining cases the vision was made neither better nor worse by operation, whether this was successful or not. In 7 cases the visual field was improved. In one case in which there was a vitreous haemorrhage 9½ months after operation it became 10° worse than it was before operation, and in the others there was no appreciable change. In 16 cases in this group the intraocular changes as a result of severe trauma made it impossible to estimate the refraction with any measure of accuracy before operation. In one case astigmatism amounting to ± 1.25 axis 15° was evident after operation; but there was a posterior corneal traumatic cataract in this case, so it is difficult to be sure whether the altered refraction was the result of operation or not. In this instance the operation of pinning back a curtain-like detachment in the upper and the lower half of the fundus (see Fig. 2) was successful, and the visual result was 6/9, with an unavoidable sacrifice of 30° in the temporal field.

In the other case there was no change in the refraction.

Results of Operative Treatment

TABLE II.—Summary of Results

Retinal Detachment Group	Successes	Failures
(1) Cystic degeneration	13 (100%)	—
(2) Choroido-retinal degeneration	21 (100%)	—
(3) Myopia	2 (67%)	1 (33%)
(4) Trauma (civil)	20 (87%)	3 (13%)
(5) Trauma (military)	10 (62.5%)	6 (37.5%)
Total	66 (86.8%)	10 (13.2%)

AMOEBIASIS: SOME DIFFICULTIES OF DIAGNOSIS*

BY

Brig. C. NAUNTON MORGAN, F.R.C.S.

Consultant Surgeon, Persia/Iraq Force; Assistant Director, Surgical Unit, and Assistant Surgeon, St. Bartholomew's Hospital, Senior Assistant Surgeon, St. Mark's Hospital

Amoebic Dysentery

Amoebiasis is a disease of military importance and, as an aftermath of the war, may well produce diagnostic pitfalls and surprises. Colonic and rectal tumours, anal and perianal ulceration, recurrent colitis, enigmatic and insidious liver abscess, are among its sequelae. The early diagnosis of amoebic dysentery is not always easy, and, furthermore, no treatment at present known is a guarantee against recurrence. There is evidence that the chance of cure bears an inverse relation to the duration of the symptoms before emetine treatment is started. Even in countries where amoebiasis is common its manifestations are protean, and the disease may exist for long periods before diagnosis is made and treatment begun.

Sigmoidoscopic Appearances.—These are varied and the lesions are often minute and easily missed. In addition to the typical discrete ulcers, which, owing to their usual position on a mound of oedematous mucous membrane, resemble a tiny pointing mouth, other changes are seen in the bowel wall. Briefly these are: scattered discrete petechial haemorrhages with no ulceration; a patch of deep-red inflamed hypertrophic oedematous mucous membrane which may be nodular to the touch; a large solitary irregular indurated ulcer infiltrating the rectal wall; diffuse proctitis with no particular characteristics except that it is usually sharply limited to the rectum.

The association of bacillary with amoebic dysentery has to be remembered. The diffuse inflammation of bacillary dysentery, with or without irregular erosions, or, in the healing stage, large irregular flame-shaped submucous haemorrhages, may overshadow amoebic lesions, which become obvious only when the former is cured. Discrete clean-cut ulcers, identical in appearance with those of amoebiasis, may sometimes be seen in bacillary dysentery. Not infrequently the sigmoidoscopic findings are indefinite and scrapings are negative, so that re-sigmoidoscopy after a course of sulphaguandine and/or emetine may be necessary.

In amoebiasis, dysenteric symptoms may be slight or absent, and amoebae may not be found in the stools on direct examination; in fact, secondary manifestations of the disease may be the first indication of infection.

Six weeks before admission a soldier developed pain in the right lumbar region, was treated, and returned to duty. Three weeks later he had persistent pain in the right chest accompanied with high fever, and was admitted to hospital. Sterile pus was aspirated from the right chest on several occasions; sulphathiazole was given. Three weeks after the first aspiration a total right empyema was treated by rib resection. Six days after the latter operation he had diarrhoea for two days, during which time the stools contained no blood, mucus, amoebae, or cysts. After drainage of the empyema the patient remained ill and febrile. Twenty-two days later (11 weeks after the first symptom) rectal examination revealed an indurated and somewhat hypertrophic ulcer, 2½ in. by 2 in., on the posterior wall of the ampulla—diagnosed as an amoeboma, though repeated stool examination had revealed no amoebae; amoebae were, however, cultured later from the stool. He was put on emetine: discharge from the empyema quickly diminished, and recovery was rapid.

Amoeboma (Amoebic Granuloma)

Medical officers working in the East are fully alive to the occasional development of a tumour of the colon or rectum resulting from amoebiasis. Repeated amoebic invasion of the colon, together with superadded pyogenic infection, may produce a progressive inflammatory lesion leading to tumour formation. The inflammatory process spreads through the bowel wall into the pericolic and perirectal fat and infiltrates surrounding structures. The tumour consists of fibrous tissue, overgrowth of granulation tissue, and varying degrees of ulceration.

The wall of the gut is destroyed and small abscesses may be present in the centre of the mass. There is considerable round-cell infiltration; lymphocytes and eosinophils are present in large numbers.

Typical amoebic ulcers may be present or, on the other hand, no evidence of amoebiasis may be forthcoming. It is likely, in the latter case, that the parasite is dwelling comfortably in the depths of the gradually growing tumour.

FIG 1—Amoebic granuloma, showing *E. histolytica* inside a blood vessel.

FIG 2—Higher magnification of area marked in Fig 1, showing *E. histolytica* lying in a small vein.

The usual sites for a granuloma are the rectum, recto-sigmoid junction, and caecum. When the mass is situated at the recto-sigmoid junction or in the ampulla of the rectum the patient complains of tenesmus and may pass blood and slime with or without faeces. An amoeboma of the rectum may be submucous and nodular, protruding into the lumen, or may take the form of a deeply indurated ulcer. The surface of the bulk of the tumour is usually smooth, but it may be irregular, friable, and infiltrating. Diagnosis from carcinoma of the rectum is difficult, and often impossible, by digital examination or by sigmoidoscopy. The dark-red nodular and ulcerated lesion looks like a carcinoma. Further, a smooth rounded non-ulcerated mass cannot be distinguished from submucous spread of a carcinoma. Even when amoebae are isolated from the stools the coincidence of a carcinoma cannot be excluded until a biopsy has been made.

A gunner aged 28 had been operated upon 10 months previously for haemorrhoids. 2½ months later he had pain on defaecation and rectal bleeding. On admission to hospital a large craggy mass was felt in the lower rectum, and *Entamoeba histolytica* was found in the stools. Emetine 12 gr. and carbarsone 0.5 g. daily for 7 days had no effect. Transferred to rectal centre: biopsy—carcinoma of the rectum; removed by combined excision.

The symptomatology of amoeboma in the colon and caecum, together with a palpable tumour, the chronicity of the disease, ill-health, loss of weight, and a filling defect demonstrated by barium enema radiograph, make the differential diagnosis from carcinoma difficult. The history of previous amoebic dysentery

* Abridgement of a paper read to the Teheran Medical Association on July 1, 1944.

In Table II I have included as a failure any recurrence of retinal detachment, however limited and slight, as indeed this was in 4 cases.

The prospect of successful surgical treatment depends much on the type of case. The prognosis is reasonably good in early cases when the retinal tear is relatively small, easily accessible, the ocular tissues are in a good state of health, and an operation by a skilled surgeon is done within a month of the onset of the detachment. It is generally better when the retinal tear is in the lower half of the eye than when in the upper. Successes in early cases are about even in hypermetropes, myopes, and low and moderate degrees of myopia.

Large and multiple retinal tears are generally unfavourable but not always so. One patient with 26 holes in a band of degenerative choroid and retina from 12 to 6 o'clock near the equator on the temporal side recovered after one operation and retained 6/9 vision. Other retinæ with large ragged rents occupying a quadrant of the eye have become reattached after operation and remained so.

The prognosis is slightly worse in deep detachments than in shallow ones on account of the distance of the retinal tear from the choroid. This is met and to some extent effectively dealt with by passing penetrating diathermy needles through the sclera and choroid sufficiently long to reach the retina but not perforate it. Interretinal fluid drains away and the detachment is shallower for subsequent diathermy applications. The prognosis is bad in long-standing cases. The incidence of success falls appreciably three months after the onset of detachment but reattachment may occur after 4 and even 10 years, particularly when the lower half of the retina only is involved.

Extensive intraocular degeneration affecting the choroid, retina and vitreous, total retinal detachment, high myopia, very low intraocular pressure and detachment in an aphakic eye, particularly when vitreous has been lost in the course of cataract extraction and vitreous shrinkage are bad prognostic signs.

Detachment on the nasal side is less serious as regards rapid extension than is the case with detachment originating on the temporal side. In the former the attachment of the retina at the optic disk affords a barrier against sudden involvement of the macula, a complication which may occur within a day or two of a detachment originating in the upper temporal quadrant. When the macula has been stripped off vision is rarely better than 6/24, and is often less than this in spite of successful reposition. Metamorphopsia may also distress the patient for some months after operation when the macula has been involved.

The prognosis is bad in cases of retinal detachment associated with persistent inflammatory lesions of the choroid, sclera, and orbital tissues (orbital cellulitis). Such cases are unfavourable to operation, and if an operation is done through mistaken diagnosis the condition is aggravated and the detachment made worse.

Poor co-operation by the patient after operation and the persistence of marked local reaction with pain are unfavourable prognostic signs. The chances of success are also less favourable in operations which are repeated, although in some cases a fourth operation has resulted in reposition of the retina, the restoration of visual field, and a fair measure of sight.

Although the number of cases due to trauma peculiar to war is small (18 in this series) these few afford an indication of the seriousness of the prognosis and the difficulties which confront the surgeon in planning an operation on an eye which is often severely damaged as a result of either contusion or a penetrating wound or both. The large splashes of blood on and sometimes beneath the retina which may organize into fibrous tissue bands and ultimately contract, the presence of large rents in the retina through which vitreous gel may have herniated into the interretinal space, and the lowered intraocular pressure are factors which militate against surgical success. In civil practice the counterpart of such cases is found in eyes with degenerative changes in the intraocular membranes and vitreous, commonly as a result of high myopia and emmetropia. As the above statistics show, such cases are for obvious reasons, rare in military practice.

Summary

This paper reviews 78 cases of retinal detachment occurring in officers and men of the Middle East Force from 1941 to 1943. The cases have been divided into five groups according to the main feature of their pathology. Seventy six were operated on by the same technique in one case operation was contraindicated and another underwent spontaneous recovery.

The prognosis is favourable in cases of retinal detachment due to cystic degeneration and to chorioido-retinal degeneration, at any rate in young men of military age. It is least favourable in war injuries. The reasons for this are discussed.

I thank Brig G. I. Scott (Consultant Ophthalmologist, M.E.F.) and Col H. D. F. Brand, Officer Commanding the General Hospital for their kind permission to publish this paper.

NUTRITIONAL IRON DEFICIENCY ANAEMIA IN WARTIME

PART III: THE HAEMOGLOBIN LEVELS OF SCHOOL-CHILDREN AND PREGNANT WOMEN IN 1944, COMPARED WITH THE LEVELS IN 1942 AND 1943

BY

L. S. P. DAVIDSON, B.A., M.D., F.R.C.P.Ed.&Lond.

G. M. M. DONALDSON, M.B., Ch.B., M.R.C.P.Ed.

S. T. LINDSAY, B.Sc.

AND

M. H. ROSCOE, Ph.D., M.B., Ch.B.

In previous papers (Davidson *et al* 1942, 1943, 1944) the haemoglobin levels of various groups of people representative of different sections of the Edinburgh population have been reported. Of these groups the two that showed the highest incidence of anaemia were the municipal primary-school children and the pregnant women. They have therefore been investigated further the last examination in the summer of 1944 being made two years after the original one. The estimation of the haemoglobin was made with the Haldane haemoglobinometer under standard conditions recommended by the Haemoglobin Survey Committee of the Medical Research Council and using apparatus which had been standardized by the National Physical Laboratory.

School-children (7-13 Years in 1944)

Children from two schools (Schools I and III, Davidson *et al*, 1944) have now been investigated on five occasions in the past two years. It has not been possible to test all the children each time, but none have been included in the present report who were not tested on the first occasion.

The mean haemoglobin levels found for the two schools on the five dates together with the number of children tested, are shown in the accompanying Table and also graphically in the Chart.

Table showing Mean Haemoglobin Levels of School-children and Pregnant Women on Various Dates in 1942-4

	1942	1943			1944 June
			June	Dec.	
<i>School I</i> Mean Hb *. St Dev	Sept. 82.9 (347) 7.2	Feb 83.1 (149) 6.8	87.1 (+0) 4.8	86.0 (110) 5.8	87.5 (237) 6.1
<i>School III</i> Mean Hb *. St Dev	July 77.5 (96) 4.6	March 81.9 (42) 6.7	87.5 (28) 6.6	85.8 (56) 5.1	90.8 (64) 5.4
<i>Pregnant women</i> Mean Hb *. St Dev	July 77.0 (64) 7.5				Jan July 86.5 (61) 7.2

Numbers of children in parenthesis.

It will be seen that there has been a considerable rise in mean haemoglobin level in the past two years, School I risen from 82.9% to 87.5%, and School III from 77.5% to 90.8%. Both these increases are statistically significant, more than twice the standard error of the mean at greater part of the time there was no significant

THE ROYAL COLLEGE OF SURGEONS

MEETING OF FELLOWS AND MEMBERS

meeting of Fellows and Members of the Royal College of Surgeons of England was held at Lincoln's Inn Fields on Nov. 16.

Sir ALFRED WILBY-JOHNSON, the President at the outset referred with satisfaction to the presence at the Council meeting of six invited representatives of special departments of practice, including general practice. Of these six four were Fellows and two were Members (one of them Dr H. Guy Dain). It was proposed that, in the Supplemental Charter which would be applied for after the war, power should be obtained to co-opt such representatives to the Council. It was obvious that representatives of special departments of practice however much their presence was desired on the Council might not be successful in the general elections of Council members and it would be grossly improper for the Council to indicate to its electorate that, for example, a radiologist or an otolaryngologist was desired. Therefore power was being sought to co-opt.

In commending the general Annual Report the President referred to the generous gift of £100,000 by Sir William H. Collins for the endowment of the department of pathology and the institution of a chair of human and comparative pathology. Dr Willis of Melbourne had been appointed as the first professor. Concerning the rebuilding of the College and the proposal to build the other Royal Colleges on adjacent sites, the possibilities of building elsewhere had been explored, but the manifest advantages of the present site in Lincoln's Inn Fields seemed to outweigh them. A building committee had been set up and an architect engaged. An appeal would presently be made to Fellows and Members. Already £12,000 had been accumulated, including a gift of £2,000 from the American College of Surgeons.

On the motion of Mr MCADAM ELLIS seconded by Mr J. B. HUNTER, the objects of the proposed Supplemental Charter were approved by the meeting—namely, to grant the Fellowship to ophthalmological candidates under special conditions, to grant a Fellowship in dental surgery, to increase the number of permitted elections to the Fellowship in each year and to render non-Members eligible for such election and to co-opt to the Council up to six additional members representative of special branches of practice.

The meeting also gave general approval to what had been done in regard to the site for the enlarged building.

The White Paper

The PRESIDENT then asked for expressions of opinion on the White Paper. He asked for first consideration to be given to the proposed administrative structure and also to the question of freedom for the profession. That freedom would be enroached upon unless independent—he disliked the word "private"—practice was preserved. Those of them who were in responsible positions had had discussions, formal and informal, with the Ministry, and he believed that they had made it plain that on the fundamental points there could be no compromise. Having taken a firm attitude on fundamentals, it was possible to give way on non-essential details.

Mr. LAWRENCE ABEL said that what they did not want was further control of the profession. Medicine would make progress in so far as it was free, not under bureaucratic control. The reform he had hoped to see was an enlargement of the present National Health Insurance which did not imply control of a free profession and left private practice untouched. Mr. DICKSON WRIGHT declared himself against the whole system of social security. He did not believe it was inevitable and he thought it should be fought. A new Parliament should deal with the matter.

The PRESIDENT agreed that it was desirable to have a new Parliament to deal with the matter, but unless there was an outcry from the people to that effect, an outcry from the profession would not carry much weight. He then asked the meeting (which numbered some 50 Fellows and Members) whether it agreed with nine points which had been tabulated by the Council as of fundamental importance. The assent of the meeting was given to each point in turn, and there appeared to be no dissent. The points were as follows—

- (1) That the administrative structure, both centrally and locally, should be modified to ensure that the medical profession had a more direct responsibility for advice and administration through nominees chosen by representative bodies of the profession.
- (2) That the scheme should not apply to the whole population, but that the general practitioner service particularly should be "provided" only for those below a certain income limit.
- (3) That contributions under a social security insurance scheme allotted to the health services should be devoted entirely to the financing of the general practitioner service, and that the hospital and consultant services should be provided for by general taxation.
- (4) That the regions for hospital administration should be large enough to provide a complete service for all purposes, and that no

existing local authority is in a position to provide such a complete service.

(5) That there should be no "direction" of members of the profession, but that they should be free to practise in places of their own choice. An adequate supply of doctors should be obtained for areas sparsely settled by offering special inducements.

(6) That the majority of the voluntary hospitals should be ensured that facilities towards the conversion of the profession into a whole-time salaried service should be resisted.

(8) That control of the profession by the Civil Service and the local authorities was not in the best interests of the people.

(9) That the facilities of Health Centres should be available for all practitioners in the district.

The Goodenough Report

The PRESIDENT then made some comments on the report of the Interdepartmental Committee on Medical Schools. He said that the report was an extremely valuable document and had assembled some information which should enable right conclusions on this subject to be reached, which did not mean necessarily that the committee itself had reached right conclusions. The Council of the College was rather disposed to quarrel with the Ministry for changing the terms of reference without informing Parliament or the College. It also disliked certain features of the report suggesting that the power of the purse should be used to enforce certain proposals, such as that every medical school should admit women, that the curriculum should be reformed before any additional grants were made for medical education (the reform of the curriculum was entirely an affair of the General Medical Council, which ought not to have pressure brought to bear upon it by a Government Department) that grants to schools should depend on the number of students attaining the degrees of the university, and that the examination fees after meeting all expenses should be devoted entirely to undergraduate assistance. The Council thought that a student who entered a great profession like this should have some proportion of his fee go to the maintenance of a headquarters which would be available to him throughout his career, particularly a headquarters like the College, which provided museum, library, research laboratories, and facilities for meetings. The Council thought that the report placed undue emphasis on academic teaching without proper regard to the value and importance of being trained in the art of medicine and surgery. "Perhaps the thing which concerns this College most intimately, and I hope will concern the whole of the profession and your great Association, Dr Dain is the tendency towards saving that there should be no other means of qualifying for the profession than university degrees. We contest that very strongly. We regard it as the duty of a great corporation like this, which through the centuries has insisted on a high standard being attained by practitioners of surgery, including a proper standard of practice after qualification, and a proper ethical standard to maintain a portal of entry into the profession which is entirely under the control of the profession and independent of any subsidized body like a university." (Applause)

He pointed out that the Royal Colleges had an international significance with an influence in the Dominions and in British possessions abroad such as no individual university could exert. On the question of clinical professors the Council took the view that a professor of surgery should not be barred from independent practice within limitations. "You are not going to get the best young men by restricting their activities in that rigid way." The Council also took strong exception to the view that all schools should be large. It had been deeply impressed by the value of the smaller medical schools, and those who were teachers knew that many men did well in small classes who would do far from well if thrown into a large class of a hundred or so. They also felt that the Goodenough Committee was unduly anxious about the number of medical schools in Central London. If London was to maintain its position as a great consultative centre its hospitals should be quickly accessible from the great London termini.

The President's remarks were endorsed by the meeting, no contrary opinions were forthcoming, and the proceedings ended with an exposition of the plans for the rehabilitated College.

EXCHANGE OF INFORMATION BETWEEN ARMY AND E.M.S.

We print this week a letter from Major-Gen D. C. Monro, Consulting Surgeon to the Army, on the subject of follow-up postcards for the interchange of medical information between Army hospitals on the Continent and the E.M.S. hospitals at home. His letter is an appeal to E.M.S. surgeons. To the Medical Research Council is due the credit not only for appreciating that such an exchange of information would be of great value to medical officers engaged in routine war medicine or surgery, or in research projects, but also for having inaugurated a system which the Army has since adopted. During the last war the M.R.C. printed a special card and distributed it free to various medical units with the B.E.F. The idea was repeated

between the levels of the two schools; but School III, which started lower, was on the final test significantly higher than School I. No explanation for this has been found. It would also appear from the figures that the increases have tended to occur in the spring months (see Chart).

Chart showing mean haemoglobin levels of school-children and pregnant women, 1942-4.

Since the same children have been tested throughout the period their average age has risen by two years, and it might therefore be thought that the rise in the haemoglobin level was due to this. That aspect has been investigated by comparing the mean haemoglobin levels of the children, divided into two-yearly age groups. It was found that the slight increase present with advancing age could not account for the rise in the haemoglobin levels between the first and final readings. No difference between the sexes was observed.

As was reported by Davidson and Donaldson (1944) children from School I were given ferrous sulphate for three months, and those from School III ferrous sulphate and ascorbic acid for six months. The improvement resulting from this treatment was apparent, especially among the younger children, up to a year from the conclusion of medication. The haemoglobin figures for these children were accordingly not included in the mean levels recorded for 1943. By June, 1944, there was no difference between the levels of those who had had treatment and those who had not, so the haemoglobin levels of both groups have been included in calculating the means for the last examination.

Pregnant Women

A comparison has been made between the haemoglobin levels of pregnant women from the same antenatal clinic in 1942 and 1944, grouped according to the trimester of pregnancy and the number of pregnancies. The results show a progressive fall in the haemoglobin level during the course of pregnancy, which was most marked in the case of women who had had three or more pregnancies. In each group the figures for 1944 are approximately 10% higher than those for 1942. Thus it was found (Table; Chart) that in 1942 the mean haemoglobin level of 64 primiparae in the second trimester was 77.0%, while in 1944 61 primiparae, at the same stage of pregnancy, had a mean of 86.8%—an increase of 9.8%.

Discussion

It is thus apparent that both the school-children and the pregnant women have in 1944 a much more satisfactory haemoglobin level than in 1942. This increase in the mean haemoglobin is due to a marked improvement in those who were most anaemic. Thus it was found that a mean increase of 11.7% had occurred in those children whose haemoglobin was less than 80% in 1942, whereas those who had a level of 80% or more showed a mean increase of only 2.6%. Or, put in another way, while in 1942 39.3% of the children had haemoglobins of 80% or less, in 1944 only 12.3% were at or below this level.

It is impossible to be certain of the cause of this improvement. It would appear from the data given in the Report of the Special Joint Committee, set up by the Combined Food

Board, on Food Consumption Levels, 1944, that there has been no material increase in the gross amounts of foodstuffs available for civilian consumption in this country between 1942 and 1943-4. Qualitatively, however, there has been an increase in the calcium, iron, and vitamin B available, the last two owing to the replacement of white flour by national wheatmeal flour. McCance and Widdowson (1940) give figures of 0.66 mg. per oz. for national wheatmeal bread and 0.28 mg. per oz. for white bread. In the course of a study of school-children's diets made in Edinburgh it has been found, using the above figures for iron in bread, that the calculated daily iron intake of children varied from 14 to 26 mg.—mean 19 mg. If the same amounts of white bread had been eaten instead of wheatmeal the iron intakes would have been from 9 to 21 mg., with a mean of 14 mg.

In Edinburgh during the past two years there have also been an increase in the number of children having school milk and an improvement in the school meals, both of which factors may have raised the protein intake of the children. The children reported on here have been divided into groups according to whether they were having school dinners or not. In December 1943, those with school dinners had improved more than those without; but by June, 1944, there was no difference in the haemoglobin levels of the two groups. The school meals thus do not appear to be an important factor. Again, whereas the school milk may have raised the protein intake of the children, the pregnant women had not received any supplementary rations when the tests were made, on their first visit to the clinic, so there is no reason to believe that their protein intake is better than it was two years ago.

For the above reasons we consider that the increase of iron in the diet has been the chief factor responsible for the rise in haemoglobin levels. It is also possible that the increase of calcium and vitamin B has facilitated the absorption of iron—either by precipitation of the phytin, the latter by improvement of absorption.

Summary

A survey of the haemoglobin of school-children and pregnant women, made in Edinburgh during the past two years, has shown that there has been a progressive rise in the mean haemoglobin levels of these two sections of the population. The cause of this rise is discussed, and evidence is put forward to suggest that the introduction of national wheatmeal flour has been an important contributory factor.

INDUSTRIAL PROBLEMS IN THE MIDDLE EAST

BY

A. MICHAEL CRITCHLEY, M.D., D.P.H.
 Lieut.-Col., R.A.M.C.

AND

I. HARVEY FLACK, M.D.
 Captain, R.A.M.C.

During four years of war industrialization has taken place on a scale hitherto unknown in the Middle East. For security reasons details cannot be given, but it may be stated that a large number of R.E., R.A.O.C., and R.E.M.E. workshops and factories have been set up for the manufacture of articles ranging from anti-tank mines to hospital bedsteads. Other large units repair and maintain tanks, guns, vehicles, and instruments. These installations have presented industrial problems varying from those met with in the United Kingdom at the time of the Industrial Revolution to tetra-ethyl-lead (T.E.L.) hazards. All this has taken place in countries with a predominantly agricultural economy and little or no pre-war industry. Many thousands of fellahin who had previously known only the bullock-cart and the ancient plough of biblical pattern have become fitters, welders, blacksmiths, and the like.

getting doctors to certify that the dermatitis had been caused by his employment.

Dr. MORGAN said he viewed the scheme with misgiving. He knew no more damaging evidence against medical tuition than was found in the Workmen's Compensation Acts. He had seen doctors and specialists go into the witness-box and make mendacious statements against the workmen. He had wondered where the General Medical Council was and why some of these witnesses were not struck off the Register. Doctors had not, in the past, been taught anything about the assessment of injury. They had to make assessments without knowing the nature of the occupation. There was no lectureship on industrial diseases in this country. Under the scheme the employers would have no urge for prevention. Take the case of the nurse. If she went to a sanatorium and got tuberculosis she could not get compensation because tuberculosis was not in the list of scheduled diseases. The same applied to scarlet fever. The only remedy for the nurse was to fight a common law action. Sir Thomas Legge had advocated the abolition of the test that a disease must be proved to be specific to the employment before it could be accepted for the Schedule. Nothing had been done. Chronic carbon-monoxide poisoning was scheduled in Australia but not in Great Britain. Vibrational diseases contracted in boot factories and road repairing were scheduled in Germany but not in Britain. Nothing in these matters was changed under the Government scheme.

Mr. PEAKE said that if the nation was to have a separate industrial scheme with special rates of benefit higher than that laid down in the general scheme, there must be a clear line of demarcation between an industrial accident and misfortunes giving entitlement to sickness benefit. The Government was prepared to consider any good alternative to the words "arising out of and in the course of the employment." He did not think the words "attributable to or aggravated by" were appropriate for industry.

The House then carried without a division the motion welcoming the Government intention to proceed with the new scheme of Industrial Injury Insurance.

Ministry of Social Insurance: Sickness Benefits

Mr. ATTLEE moved on Nov. 11 the second reading of the Social Insurance Bill. He said the Bill was designed to transfer to a single Ministry of Social Insurance powers now divided between the Minister of Health, the Secretary of State for Scotland, the Minister of Labour, and the Home Secretary. These powers were contained in the Acts of Parliament and many regulations. The appointment of this Minister and transfer of powers would enable the new scheme to be brought more quickly into legislative form. The Minister would have the task of framing legislation and working out administrative changes and would have at his disposal the trained staff now dispersed between various Departments. Clause 6 of the Bill laid down the powers and duties hitherto belonging to other Ministers which were to be transferred by Order in Council. Provision of medical benefits remained with the Minister of Health.

Mr. GREENWOOD said the social insurance scheme was not merely a scheme for co-ordinating the payment of insurance benefits. Behind the scheme was a close association of constructive treatment with payment of benefits.

Col. ELLIOT said that on the divorce of the handling of insurance finance from the payment of health benefit the Bill was obscure. The ideal of associating rehabilitation with health insurance had never properly been carried out. The Ministry of Health Act had torn medical research from the insurance scheme and put it under the Lord President of the Council. He understood there was no proposal that it should be integrated again. By an Order in Council under the new Bill powers could be taken away from the insurance authority in Scotland and concentrated in London. Lord Addison once acclaimed the uniting of health insurance with local government and housing. Now a cry of delight went up at their separation. Col. Elliot saw no reason why the Chief Medical Officer of Health should not be found a further place in the proposed legislation. Sir Wilson Jameson had lately said that there was no means of assessing the day-to-day health of over 40,000,000 people. But he was getting medical certificates daily about millions of those people. Proper use had never been made of those certificates, and the Bill, if anything, would push them further into pigeon-holes.

Sir DAVID MAXWELL-FYFE said the Government desired that there should be co-operation and co-ordination between the Ministry of Social Security and the other Departments which would work, for example, the rehabilitation proposals. What Col. Elliot had said about regional devolution would receive the attention of the Government. For the National Health Service the Minister of Health would continue to be responsible.

Provision of its benefits must lie within his purview. Services in kind came under the Minister of Health; services in cash would be transferred to the Ministry of Social Insurance. The Ministry of Health must keep control and administration of medical services.

The Bill was read a second time without a division.

Demobilization of Doctors

Mr. ERNEST BEVIN announced on Nov. 15, when replying to a debate on release from the Forces, which had been opened by Col. Protomo, that doctors and dentists would be released from the Forces by age and length of service, in accordance with the general scheme. Mr. Bevin asserted that after the 1918 election such political pressure was used to get individuals from the Forces out of their turn on the plea of being specialists that the whole demobilization scheme broke down. The Ministry of Labour must examine the figures of what they would get released under Class A before it began pressing for any special people. With regard to the universities a large number would come back under Class A. The Government would then have to see what number was necessary to supplement them. The further educational training scheme would give a person in the profession a chance to take courses to make good the break in his training.

Dr. HADEN GUEST said weight should be given to the wounds a man had suffered, the illnesses which he had suffered, and any changes in his medical category. In Burma the admissions to hospital for the most part for serious tropical diseases, increased by 100% in the year. These things should be considered in relation to the theatre of war in which the man had been, when deciding time and priority of demobilization. Dr. Guest said he did not know how the Government was going to release a large number of doctors. It had not the doctors. The proportion of doctors engaged in the Services was larger than the proportion of miners or of building workers. There were not, in fact, enough other doctors to release them according to age and on the lines laid down in the White Paper. Unless plans were being made for the more rapid bringing forward of new doctors and for obtaining others for the civil population of this country Parliament would not be able to tackle the question of Forces doctors as it should be tackled.

Domestic Staffs of London Hospitals

In a reply on Nov. 16 to Mr. Keeling, Mr. BEVIN said he knew of the shortage of staff in the London hospitals. During the period of the heavy "flying-bomb" attacks the London hospitals evacuated a large number of their patients and their staff demands were much reduced. In the last two months these demands, enlarged by the need to replace excessive wastage consequent upon the dislocation caused by the bombing again became urgent. This coincided with the need to provide domestic staff for the hostels for building workers brought into London to repair bomb-damaged houses, a measure pressed from all quarters as one demanding the highest priority. Some 3,400 domestic workers had been found for these hostels. Even during this exceptionally difficult period the hospitals were not neglected. In the past two months 63 cooks, 756 full-time and 115 part-time domestic workers, and 163 orderlies, porters, stokers and maintenance men were placed. Of 62 domestic vacancies notified from Aug. 23 to Nov. 7, 51 applicants had been submitted and 44 placed. Further demands had since been received. Now that the staffing of the building workers' hostels was almost completed it should be possible to make further progress in meeting the demands of hospitals. These would enjoy first priority for the supply of domestic labour. Mr. Bevin appealed to the voluntary hospitals in London to introduce more up-to-date personnel management. He said he would be helped if their staffing measures were not so antiquated. He added that in regard to cooks and staff there was first priority for hospitals all over the country.

Charge for Certificates.—On Oct. 31 Mr. ROBERT MORRISON asked the Minister of Health by what authority doctors charged their panel patients a fee of 1s for signing their certificates for priority milk and eggs. Mr. WILLIAMS replied that insurance medical practitioners were required to give medical certificates only for the purpose of the National Health Insurance Acts. They were not forbidden to give and charge for certificates required for other purposes.

Antimalaria Tablets for S.E.A.C.—Asked on Nov. 7 whether antimalaria tablets and water-sterilizing powder were now available to all ranks who were in need of them in S.E.A.C., Sir JAMES GRIGG said these preparations were supplied to South-East Asia Command by India, and so far as he knew all demands had been met.

Notes in Brief

Mr. Ernest Bevin, on Nov. 2, told Dr. Russell Thomas that he was unable to state his intentions on the demobilization of students who had not completed their professional examinations.

Equipment and machinery for the most part have had to be imported and have often arrived broken or with parts missing or have been lost at sea. Production lines have had to be created in buildings never intended for industrial use. Huge workshops have appeared covering many square miles of desert. Environmental difficulties have further complicated this remarkable industrial expansion.

Environmental Difficulties

Operational needs led to the siting of many War Department factories in unhealthy spots, in overcrowded slums, in malarious swamps, and in some cases near primitive native villages. Steps were always taken to improve the factories and to reduce the amount of dirt, flies, mosquitoes, and other insects. So far as was possible British personnel have been protected against typhoid, smallpox, and typhus. In the case of native employees, protection has been afforded against typhoid and smallpox, and regular disinfection has been arranged. In some cases lethane belts have been of value in keeping natives louse-free, but they lose their efficiency after 14 days. No skin sensitivity has been noted in Egyptian labourers, but British personnel have often suffered from intense irritation after using these belts.

Even though the native workers usually return to their homes each evening regular monthly disinfection has reduced both the number of louse infested men and the degree of infestation. Records kept at one disinfection centre showed the following figures:

Proportion of Men found Louse each Month before Disinfection

1943					
January	80%	May	20%	September	4%
February	80%	June	18%	October	11%
March	40%	July	9%	November	12%
April	46%	August	5%	December	12%

These precautionary measures have had a marked influence in preventing disease. During the twelve months under review approximately 43,000 cases of typhus were notified in Egypt, the majority in Cairo. Yet in Cairo area factories under our supervision an average 4,000 British troops working in the closest contact with 20,000 employed civilians, there were only 4 British and 21 native cases of typhus during the year—compared with an estimated rate of 2.5 per 1,000 population over the same period. All our cases were in the first six months of the year—before typhus vaccine was available for general inoculation.

Even in Cairo standards of sanitation were low. Whole districts were without any water carriage system, and promiscuous and indiscriminate defaecation was customary. Proper conservancy systems were invariably installed, and, in addition to being taught their work native employees were "house-trained".

Ventilation and lighting have given rise to various problems. The intense summer heat has necessitated the provision of double roofing for many workshops. This simple measure lowers the internal temperature by several degrees. The provision of fans has been restricted owing to shortage. In some factories the ordinary fan has been entirely contraindicated owing to the danger of an electric spark causing an explosion. In such shops ventilation has been maintained by extractor fans installed on the exterior of the building. The constant sunshine experienced in Egypt has rendered the daylight illumination of most factories good, but nocturnal lighting has been difficult owing to the shortage of high-power electric bulbs. In the former civilian factories taken over, the illumination had to be modified and improved in the majority of cases. The latest machinery, which had just started to arrive in the Middle East, is usually self-lighted by adjustable lamps. In an underground basement where ATS were operating mechanical accountancy plant the provision of daylight type artificial illumination reduced the incidence of cases of headache and eye strain from over 20 to less than 5 a week.

The shortage of British man-power has led to the posting of many men of low medical category to base installations, and great care has to be exercised by medical officers to ensure that the physical defect is such that it will not interfere

with the efficiency of a man's work, will not be aggravated by the nature of his employment, and will not render him specially prone to industrial diseases. Thus, men down graded on account of dermatoses or chronic pulmonary disease have had to be weeded out after posting to TNT factories. Similarly, care has been taken in the selection of native workers, but employees have been accepted for non-hazardous occupations at a much earlier age than would be legal in the United Kingdom. These juveniles have proved most efficient workers and their health has benefited by the greatly improved nourishment resulting from the wages they earn.

In spite of linguistic difficulties Egyptian labourers have speedily been taught to use complicated machinery, and have developed considerable skill, while their capacity to work for prolonged periods without evidence of fatigue surpassed that of the British personnel. Particularly did this apply to monotonous repetitive work. In general, the native labourer was found to be unadaptable. While quickly learning one job, he cannot be switched over to a different task with any degree of success. This inability to accommodate himself to fresh work has prevented the rotation of labourers in hazardous occupations. The usual British practice of never keeping a worker who is exposed to industrial hazard on a dangerous task for very long but of switching him on to a safe post at regular intervals, has been tried many times with native workers but has had to be abandoned. This non-adaptability has resulted in natives being kept on highly dangerous tasks for 8 to 12 hours daily for many months and a high incidence of toxicosis was expected. These fears have, with one exception, proved groundless and the resistance of the native epidermis to such toxic substances as TNT, lead, and various oils has been most noticeable.

Industrial Fatigue

In one huge tank workshop near Alexandria 300 British 'other ranks' were closely studied over a period of eight months in 1941. They were subjected to prolonged fatigue for 18 consecutive weeks during which they had no leave and no days off. The actual hours worked ranged from 72 to 84 a week. The main points that emerged from this study of 1,467 cases of sickness or injury involving a wastage of 8,770 man days were as follows:

First, sickness, disability, and injury rates were increased by the period of prolonged fatigue.

Secondly, the extent to which sickness was thus increased was much the same in the Army in Egypt as in civilian employees in the United Kingdom, despite a much closer control of feeding and housing arrangements than is ever possible among civilians.

Thirdly, the nature of this sickness was similar to that which follows fatigue in the United Kingdom. The principal cause of wastage of man-power was the common cold. The next most important cause sandfly fever, may be regarded as an Egyptian condition corresponding closely to influenza. Infections of areolar tissue and those diseases of the skin which cause invalidism were also manifestations of a lowering of the general resistance. Combined with this was a steady increase in minor and major injuries, especially at the end of the working day.

Fourthly, the most potent 'psychological incentive' operated for just so long and no longer. In this group of men "just so long" was about four weeks. At the beginning of this study the working week was increased suddenly from 56 to 80+ hours, and there was at that time a considerable 'psychological incentive'. The work was done and there was no significant increase in sickness rates till just over four weeks later, when the steady rise in the incidence of sickness began. An exactly similar situation arose again, and there was the same time lag.

Accurate recording is essential in this kind of study and it was found useful to have two or more different records which could be cross-checked, and which showed the same material from different angles. Absolute figures for new cases, man days lost, and so on were difficult to bring into perspective. Percentage figures—relating, for instance, the man-days lost to the man-days that might have been worked assuming no sickness of any kind—gave a truer picture. But what appeared to be the simplest and most sensitive index of general health in a group of men was the average disability period, a figure which was worked out each month. This figure was arrived at by dividing by the number of cases under treatment

ketonuria. When the fat in the diet was increased gradually, glycosuria disappeared without the appearance of ketonuria (except on one day in 8 weeks). The amount of diet eaten containing 70% of added fat provided 90% of the calories available in the amount of normal diet eaten; and maintained body weight.

After successive periods of high-fat diet the glycosuria seen on return to the normal diet steadily diminished.

ANTIBACTERIAL ACTION OF 2-AMINOPHENOL (O-AMINOPHENOL)

BY

MARY BARBER, M.D.

AND

G. A. D. HASLEWOOD, M.Sc., Ph.D.

(From the British Postgraduate Medical School and Guy's Hospital)

In the course of work with a compound between cholic acid and sulphanilamide we discovered that some intermediate substances devoid of sulphanilic groups had a greater activity against Gram-negative bacilli than the final compound. This led to the investigation of a series of compounds for their activity against this group of organisms. Although the investigation is still in progress this paper records the results obtained with 2-aminophenol, as they appear to warrant its trial as a local antiseptic.

The use of sulphonamides and penicillin has brought to light the need for adequate chemotherapeutic treatment of infections due to or kept up by such organisms as *Proteus* and *Ps. pyocyanea*. Acridine derivatives are perhaps the most effective in this respect, although these compounds are toxic to leucocytes and tissue cells. McIntosh and Selbie (1944) recommend a powder consisting of 1 part proflavine and 99 parts sulphathiazole, and claim that it affords protection against pyogenic cocci, clostridia, and Gram-negative bacilli. Recently a group of compounds classified as synthetic detergents have been recommended for local antiseptics. Their action *in vitro* was described by Baker *et al.* (1941), who showed that the cationic detergents had a significant effect on Gram-negative bacilli, although this was less pronounced than their action on Gram-positive organisms. Two of this group—C.T.A.B. and phemeride—have received a clinical trial. The action of C.T.A.B. has been studied by Barnes (1942) and Williams *et al.* (1943, 1944), but unfortunately its antibacterial action is drastically reduced by the presence of organic matter. Phemeride has been shown by Hland (1944) to have an antibacterial action stronger than that of C.T.A.B., to be effective in the presence of 50% blood, and to be relatively non-toxic to the tissues of the body. Unfortunately both these compounds are very much less active against Gram-negative bacilli than against the pyogenic cocci. For the treatment of *Ps. pyocyanea* infections Berry (1944) and Gough *et al.* (1944) have recommended

ethylene glycol monophenyl ether (phenoxetol), which, although a rather feeble antibacterial agent, appears to be particularly active against this organism.

Experimental

In the following experiments proflavine (2:8-diaminoacridine sulphate) has been tested in parallel with 2-aminophenol in order that a comparative picture can be obtained. 2-aminophenol is readily soluble in water. Fresh aqueous solutions have a pale-brown colour which deepens on standing, and after a time a slight precipitate forms. In spite of this well-known instability to oxygen and light there is no appreciable difference in bacteriostatic activity between fresh and 7-day-old solutions.

Bacteriostatic Action in Broth.—Serial dilutions were made in broth and then a suitable inoculum of the organism to be tested was added to each tube. Most of the tests were carried out in broth at pH 7.5 containing 1% "lab-lemco," 1% peptone (B.D.H.), 0.5% NaCl, and 0.005% *p*-aminobenzoic acid. Variation of media, however, did not materially affect the results. Table I shows the

TABLE I.—*Bacteriostatic Action in Broth at 37° C. (Size of Inoculum less than 500 Organisms in Each Case)*

Organism	Limiting Dilution of Chemical causing Complete Inhibition of Growth			
	2-aminophenol		Proflavine	
	1 Day	7 Days	1 Day	7 Days
<i>Bact. typhosum</i> ..	32,000	16,000	64,000	64,000
<i>Proteus vulgaris</i> ..	32,000	32,000	64,000	64,000
<i>Ps. pyocyanea</i> ..	8,000	4,000	8,000	4,000
<i>Staph. aureus</i> ..	64,000	32,000	64,000	64,000
<i>Str. pyogenes</i> ..	64,000	64,000	500,000	500,000

bacteriostatic activity of 2-aminophenol and proflavine obtained with various bacteria when a small inoculum of less than 500 viable organisms was used. Some variation in results occurred in different experiments with 2-aminophenol; the figures given represent an average. The activity of proflavine was rather more constant.

Table II shows the results obtained with *Staph. aureus* when inocula of 3.4 million, 34,000, and 340 viable organisms respectively

TABLE II.—*Effect on Antistaphylococcal Action of Varying Size of Inoculum*

Size of Inoculum of <i>Staph. aureus</i>	Limiting Dilution of Chemical causing Complete Inhibition of Growth			
	2-aminophenol		Proflavine	
	1 Day	7 Days	1 Day	7 Days
340 viable organisms	128,000	32,000	128,000	64,000
34,000 " "	32,000	32,000	64,000	64,000
3.4 mill. " "	4,000	4,000	64,000	32,000

were used. As will be seen, 2-aminophenol is very much less active against a large inoculum than against a small one, whereas the activity of proflavine is not so greatly affected by the number of organisms.

Bactericidal Tests.—Suspensions of organisms in 2-aminophenol and proflavine respectively were made, such that the final concentration of chemical was 1:1000 and the number of organisms per ml. about 20 millions. The tubes were left at room temperature, and viable counts were made after 6 hours and 24 hours. In a typical experiment with *Bact. typhosum* the original concentration of organisms was 17.5 millions per ml. After 6 hours 5.5 millions

TABLE III.—*Effect of 2-aminophenol and Proflavine on Str. pyogenes in Human Blood in Slide Cells*

	Fresh Debrinated Blood							Blood in 1:1000 Liquid				
	2-aminophenol							Proflavine

No. of organisms per slide cell	0	0	0	0	2	2	2	0	0	32	35	28
Dilution of chemical	1/100,000	1/200,000	1/400,000	1/800,000	1/1,600,000	1/3,200,000	None	1/100,000	1/200,000	1/400,000	1/800,000	None
No. of organisms per slide cell	0	0	1	1	2	2	2	0	30	35	35	28

in any one month the sum of the days during that month on which they were treated. Thus, if five individuals were treated during one month for two, seven, three, six, and five days respectively, the sum of these days is twenty-three, and the average disability period for any one of these five cases is 4.6 days. This figure, of course, was irrespective of the clinical condition for which the men were being treated. It was an index of the rapidity of recovery of the group as a whole from disease or injury of any kind. The point is well shown by the following comparative figures in this particular group of 300.

Month, 1941	New Cases	Man-days Lost	Average Disability Period
March	89	358	4.0
April	123	540	4.4
May	187	855	4.6
June	225	1,156	5.1
July	275	1,573	5.8
August	302	2,147	8.1
September	163	912	6.2
October	110	599	5.5

The hours of work were increased in early April, and the period of long hours continued till the middle of August. It is perhaps worth noting, too, that with shorter hours and men on leave a maximum output of tanks was achieved in October; this was bettered in November, and the output reached a new record figure in December.

Certain conclusions were put forward tentatively after consideration of these records.

1 Young healthy adult males who are well fed, well housed, and well cared for can work effectively for long periods without showing signs of strain or ill-health provided that their hours of work do not exceed 60 a week. This is a maximum and not an optimum figure. The optimum may well be appreciably below 60 hours a week.

2 If such men are made to work more than 60 hours a week for more than four consecutive weeks there will be a rise in the incidence of sickness and disability among them. This rise will be due to conditions of minor ill-health—typically the common cold—associated with a lowering of the general resistance to disease, and will continue, and increase, until such time as the hours of work are reduced again to a figure below 60 a week.

3. Where a group of men has a high rate of sickness due to a prolonged period of fatigue from overwork, steps should be taken at once to reduce the hours of work to below 60 a week and to grant leave. No other measures will affect the situation appreciably.

4. The most potent "psychological incentive" will not keep a large group of men in good health if that group is working more than 60 hours a week for a longer period than four weeks.

As a result of this study the many large R.A.O.C. and R.E.M.E. installations in the Middle East were all instructed to work a 57-hours week. In emergencies these hours were occasionally increased, but never for more than three weeks. The system of recording sickness rates was also generally adopted.

Methods of Recording Sickness

This method of recording sickness is being described in full elsewhere by one of us (I. H. F.). Briefly, a daily note was kept of "all sick." This included every man not 100% effective. Thus men receiving specialist treatment of any kind were included, as were men doing a full day's work but under treatment for, say, corns. Cases under this heading would range from men in hospital or on sick leave, through the "excused all duties" and the "light duties" group, up to men returned to duty that day. This figure was related daily to the ration strength of the unit and expressed as an average weekly percentage figure to the nearest one-half per cent.

This method was applied to all R.A.O.C. and R.E.M.E. base installations in the Middle East. Records were kept by companies (usually 300 to 400 strong). In all companies and in widely differing areas the usual figures were below 5%. A local epidemic of, say, sandfly fever might bring the figure up to nearly 10%, but that happened rarely. In the company previously referred to the figure ranged constantly from 3 to 4%. In 18 weeks of prolonged hours of work there was no appreciable effect for four weeks. After that period the sickness rates rose steadily to just over 30%. At that point

hours were reduced and leave was granted, but it was six months before the weekly figures had returned to the usual level below 5%.

Major and Minor Injury Rates

It was not possible to record sickness rates among civilian native employees, as the Army does not accept responsibility for the treatment of diseases other than the essentially industrial; but over the last two years injury rates have been recorded. Injuries were classed as major—i.e., involving injury pay of some kind—or as minor; in the latter case they were trivial injuries treated by native medical orderlies. The orderlies had all to be trained, and they were given first-aid supplies according to scales depending on the number of men employed, type of work, usual nature of injury—cuts, burn, eye injuries, etc. All injuries were recorded as major or minor and rates were standardized to the number of injuries per 100 employed civilians per month.

Major Injuries

Table I compares major injury rates in two base workshops each employing over 7,000 civilians. One installation was engaged on the production of war stores ranging from ration-boxes and refrigerators to gun-mountings and blast-furnaces. The other was concerned with the repair and maintenance of all types of instruments, guns, and vehicles.

TABLE I.—Major Injury Rates per Month per 100 Employed

	1942			1943								
	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sep.
Production	2.2	2.9	2.1	2.9	2.6	1.9	1.6	1.4	1.8	2.0	1.8	1.2
Repair and maintenance	4.4	4.4	3.1	4.2	4.1	4.2	3.2	3.1	3.6	3.2	2.6	1.9

These figures represented 1,759 major injuries in a year among an average civilian strength of 7,192 on the production side. The corresponding figures for the repair and maintenance installation were 2,972 major injuries with an average daily strength of 7,166 civilians. As anticipated, more injuries occurred on the repair side than in straight production; but in both cases there was an improvement over the year, due to the adoption of different safeguards and also to the increasing skill of the natives employed. The rise in June, 1943, was due to a rush of work essential to the Sicilian campaign.

Minor Injuries

In each of 24 sub-workshops—factories ranging from units of 100 to 3,000 civilians with a sprinkling of British troops as overseers—minor injury rates were similarly recorded and standardized to the rate of minor injuries per month per 100 employed. These were trivial injuries—cuts, abrasions, burns, etc.—treated by the native orderlies and rarely seen by a medical officer. These figures brought out clearly several points of interest.

Effect of Increasing Skill.—Three shops, each employing some 300 natives, were engaged on the production of wooden articles—tables, chairs, packing-cases, ice-boxes, ration-boxes, desks, etc. Shop No. 1 had been in existence in peacetime with much the same employees. Shop No. 2 was a wartime creation, and at the time of this study most of the native employees had been engaged on the same job for over twelve months. Shop No. 3 had been started two months before, and all the employees were new recruits and learnt their jobs the hard way. Table II shows the injury rates in these three different groups—each of similar size and engaged on much the same work.

TABLE II.—Minor Injury Rates per Month per 100 Employed

	1942			1943					
	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	May	June
Shop No. 1	15	17	14	11	10	12	16	11	12
Shop No. 2	26	25	31	28	30	27	29	25	27
Shop No. 3	81	59	47	41	43	33	37	34	31

The same point was shown equally well in a shop (No. 4) in which the average civilian strength leaped from 600 to 1,200 in the first week of March, 1943 (Table III).

Shop No. 5, which showed very constant figures, was a peacetime workshop employing over 3,000 natives, making hospital beds, Soyer stoves, and the like. In this shop expansion took place early in the war, and as it was in an isolated district its employees, once they had moved to this area with their families, tended to remain. Frequently the injuries have been of the "avoidable" type. Thus

P. D. Wilson) of *Fractures and Dislocations*, 1928, and of a textbook on *Orthopaedic Surgery*, 1926.

A first-rate golfer, he was well known on Edinburgh and East Lothian courses as a prominent player in club competitions up to the outbreak of the war. Tribute to him as sportsman and friend, and as pioneer in the development of orthopaedic surgery in Scotland, has been paid by a colleague writing in the *Scotsman*.

We regret to announce the death on Nov. 9 of Dr. WALTER MARTIN ASH, O.B.E., county medical officer for Derbyshire. He was born at Castle Cary, Somerset, on March 27, 1889, and from Blundell's School, Tiverton, went to the London Hospital. During student days he played rugby football for his hospital and for Somerset. He graduated M.B., B.Sc. with honours in anatomy and physiology in 1912, held five resident posts in succession at "the London," and served throughout the last war as temporary surgeon lieutenant, R.N. In 1920 he obtained the D.P.H. of Manchester University after taking a course in sanitary science there, and entered the Public Health Service; before his promotion to the senior Derbyshire post he had been assistant county M.O.H. for Lancashire and school medical inspector, and deputy county medical officer for Middlesex. Dr. Ash took the F.R.C.S.Ed. in 1923. He published a report on concurrent vaccinia and variola, and articles on goitre, on hereditary microphthalmia, and on school closure in mild smallpox epidemics. He was awarded the O.B.E. for services to Civil Defence in the Birthday Honours list of 1943. Dr. John Cahill writes: One morning in 1941 Dr. Harold Fernandes, medical superintendent of Derbyshire County Sanatorium, informed me that Dr. Ash was to call that day on a visit of inspection. I received the news with very mixed feelings indeed. The efficiency of Ash was almost a legend, and, in addition, he was reputed to be somewhat of a disciplinarian. I was to discover, however, that this man of masterful manner and rather severe expression knew how to unbend on occasion. Although his health was at that time seriously impaired, no one less like an invalid could be imagined. His conversation raced through memories of Russell Howard, memories of days spent at cricket and football, and memories, amusingly humiliating perhaps, of sparring bouts in which the late Jim Driscoll, round after round, had prevented him from landing a punch. Later, we saw quite a lot of him and always looked forward to his visits with pleasure. Ash, a former surgical registrar, retained a keen interest in surgery and loved to steal occasional hours from his work to watch operations. He once said that *Gray's Anatomy* was his favourite bedside book (a choice which I found altogether strange). He also possessed the rather uncommon gift of leadership (in the good sense of the word), as a result of which he maintained almost a family spirit among the medical officers of the Derbyshire County Council.

WILLIAM MCCREADY, F.R.C.S.I., who died at his residence in the Ulster countryside on Oct. 29, was the third son of the Rev I. M. McCready (himself a graduate in medicine), Rector of Magheradroll, Co. Down. Born in 1880 he was educated at "Inst." Belfast, and Trinity College, Dublin, where he took his B.A. degree with a senior moderatorship and gold medal in English literature. Entering Queen's College, Belfast, in 1902 he qualified M.B., B.Ch. in 1907. After a term as resident in the Royal Victoria Hospital he studied ophthalmology and otology in Vienna, and on his return in 1910 was at once appointed ophthalmic surgeon to the Belfast Hospital for Sick Children and assistant surgeon to the Ophthalmic Hospital to both of which he was consulting surgeon at the time of his death. In the war of 1914-18 he served as assistant officer with the 10th Battalion, Royal Irish Rifles, 1916, when he was transferred to the R.A.M.C., to act as ophthalmic specialist. In 1933, much to the grief of his friends and patients, a serious breakdown in health forced him to retire from practice, and he went to live in a small cottage overlooking the waters of Strangford Lough which he had bought some years before. There he and his charming daughter, who had a generous hospitality to their host of friends, and who was herself "ruffled" with a serious case of rheumatism, continued to live. It became the customary thing "to run down" to see him for an hour, sure that this would mean a return to work with a different outlook on things in general. Before his retirement yachting was his principal hobby, and there is something fitting in the fact that he died quite suddenly while typing out the log of one of his last cruises up the West Coast. The sympathy of the profession in Northern Ireland for his widow and only son, now serving with the C.M.F., is a well-remembered and widespread—R. H.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 25.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

many of the "foreign bodies, eye" injuries would not have occurred if the victim had used the eye-shields provided. It may be worth noting here that almost all British cases of "F.B. eye" were back at work within 48 hours, whereas natives sustaining the same injury were as a rule off work for 5 to 7 days. This is a difference easily applicable in a country in which some 90% of the population have rachmatous eyes. Another prevalent avoidable injury has been worn of the feet, due to the practice of working bare-footed in foundries and blacksmiths' shops. Boots were provided for these workers, but it took some time to teach them that they should be worn on the feet and not dangling round the neck.

Specific Hazards

There was a risk of plumbism in some installations; the chief of which were (i) battery reclamation, (ii) petrol storage, (iii) printing.

Battery Reclamation

In the reclamation of batteries the following processes are carried out: (a) Preparation of metal by breaking down old accumulators with the lead run out in a reducing furnace:—This is done in the open, hence is not very dangerous. (b) Casting of plates:—The lead is melted in a cauldron and poured into moulds. The danger from fumes has been minimized by the provision of hoods with extractor fans. (c) Pasting:—The paste is made by mixing litharge, red chromate, and a binder manually, as a mechanical mixer is unobtainable. The risk of inhalation and skin absorption of lead is very high. The paste is introduced into the prepared frames with a hand spatula. Dust has been lessened by keeping the floors, benches, etc., constantly damp, but the risk of absorption through the skin prevails, as gloves have been found useless. (d) Drying:—The plates, having been pasted, are dried in a chamber heated by fumes from the cauldron in the casting-room. As this room is only entered for the purpose of adding or taking out plates, the danger from inhalation of a lead-impregnated atmosphere is of short duration. (e) Forming:—The dry plates are immersed in weak sulphuric acid and charged with electric current. This process is carried out in a large well-ventilated room, so that a high concentration of fumes is not obtained. (f) Mounting:—The charged plates, or electrodes, and the electrolytes are now brought together to make the accumulator, the plates being placed vertically in the cells suspended by hooks and separated from each other by insulating-rods. They are then fixed to the cover and external connexion by lead soldering. During this process lead fumes are evolved from the solder.

Careful watch has been kept on the physical condition of the employees, and during two years' service no cases of lead poisoning have been detected. This is remarkable; for if, in the United Kingdom, men had worked under similar conditions there would have been many cases—some probably fatal. The only time when there has been any suggestion of symptoms due to lead was during Ramadan. At this time, for 28 days, no practising Moslem eats or drinks while the sun is up. Thus any inhalation or ingestion of lead dust is taken in a pure state, not being diluted by the presence of water or food in the stomach. During this time the number absent without leave rose, and the usual complaint was gastric upset from keeping Ramadan. Investigation revealed the following facts, which bear out the theory that this sickness was caused by mild degrees of plumbism.

Work	Average No. of Days Absence per Employee			
Pasting	3.2
Casting	1.0
Charging	0.6
Assembly	0.5
Stripping	0.5

This order corresponds with the danger from plumbism, except in the case of charging or formation, in which the inhalation of sulphuric acid fumes would tend to cause gastritis. Blood counts of workmen employed in the most hazardous processes for over a year revealed no abnormality excepting a 70% haemoglobin level, which is a figure considered well above the average among the Egyptian working-class.

T.E.L. Hazard

In the summer of 1943 eleven natives in one civilian petrol installation died as a result of acute T.E.L. poisoning. All became maniacal at some stage of the brief illness. The factors leading to this situation were as follows:

1. The work of filling 4-gallon "jerricans" from a feed-pipe with taps opening off it was done in a small building with no ventilation whatsoever. Since this was done at night there was a complete black-out, and because of the danger of fire there was a blast-wall entirely covering each door and window.

2. This was the hottest summer in Egypt for the last 34 years.

3. T.E.L. concentration in the petrol had just been increased from 2.6 to 4.8 c.c.m. per imperial gallon.

4. In view of the Sicilian campaign this plant was working 24 hours a day seven days a week, and because of the shortage of labour two 12-hour shifts were operated. Or, in other words, at one and the same time these natives were subjected to minimal ventilation, maximal heat volatilization of T.E.L., and maximal periods of exposure—with disastrous results.

Either 70- or 80-octane petrol was in general use at this time, both grades containing enough lead to need precautionary steps. An investigation had already been made into all W.D. petrol stores to ascertain the hazards and apply the appropriate precautionary measures. Three additional main sources of possible poisoning had been detected: (a) Washing of cans:—The cans are washed with petrol, and the washer gets his clothes saturated with petrol. (b) Storage in underground sheds:—Some of the tins leak, with the result that the sheds are filled with fumes. (c) Sealing of "leakers":—Leaking tins are filled with petrol and the leak is soldered.

Precautionary measures adopted included careful selection of personnel, regular medical examination, provision of overalls, showers, and daily milk to handlers, external storage of petrol, and substitution of 70-octane petrol for washing cans.

Printing Presses

Most of the W.D. printing presses have been taken over from civilian owners. In none of the British or native employees at these presses have we ever noted anything even remotely suggestive of lead poisoning.

Over the last three years we have observed natives at risk from T.N.T., lead, T.E.L., Diesel oils, and other industrial toxic substances for long hours each day over long periods. In the T.E.L. incident quoted, toxic effects were almost entirely due to inhalation. In all other cases we were constantly impressed by the way in which the native epidermis seemed impervious to lead, T.N.T., and a variety of oils.

Summary

A few of the difficulties and problems following the introduction of W.D. workshops and factories into the Middle East are reviewed.

Methods of recording sickness and accident rates are discussed, with some notes on the relation between fatigue and sickness.

Problems associated with special hazards are described.

A CLASSIFICATION OF DEATHS OF MEDICO-LEGAL IMPORTANCE

BY

I. GORDON, M.B., Ch.B.

(Department of Medical Jurisprudence, University of Capetown)

For many years deaths of medico-legal importance have been classified into three groups according to the cause of death—viz., coma, syncope, or asphyxia. Three series of pathological changes have been described as characteristic of these types of death. In particular the post-mortem signs of asphyxia have always been regarded as forming a distinct pathological entity.

I have analysed the results of many hundreds of necropsies in order to determine whether asphyxial deaths can be differentiated from other deaths of medico-legal importance on the basis of a qualitative difference in the pathological changes. The conclusion I have drawn is that reliable differences cannot be detected on the basis of morbid anatomical observations alone.

In all forms of death of medico-legal importance the findings at necropsy may be divided into two groups. The first group comprises the basic pathological changes of circulatory failure such as visceral congestion and capillary haemorrhages. These non-specific changes are always present in greater or less degree in deaths from any cause. The second group consists of the pathological changes which are dependent on the type of death—e.g., the local injuries to the neck in throttling and strangulation, and the colour of the blood in acute carbon monoxide poisoning. Such changes are best described as special pathological changes. It would appear that a sufficiently clear

suggested that the spermatogenic cells may have some internal secretion, but all the evidence shows that testosterone comes from the interstitial cells; "a direct hernia never passes into the scrotum": this statement is definitely erroneous, although it has been copied from book to book since it was first made. Then what is the student to do about erysipelas, to which we could find no reference except that it is "indistinguishable from reticular lymphangitis"—a true statement but scarcely sufficient as an answer to an examination question? Perhaps, however, this is now regarded as a medical disease. We consider the index of a student's textbook to be one of its most important parts, yet these 700-odd pages are provided with but 6 of index, so that, to take the above quotations as examples, erysipelas, arsphenamine, testosterone, and reticular lymphangitis are looked for in vain.

There are a good number of line illustrations (unnumbered) of considerable merit. Unfortunately, owing to the printing of the book upon wartime paper, the skiagrams have had to be reproduced as black-and-white drawings, which detracts from their value and may mislead the student when he is confronted with the real article. The whole book gives the impression of having been hastily written, but it is very much to be hoped that future editions will conform more closely to the excellent ideals of the preface.

SEX EDUCATION FOR THE YOUNG

Sex Education. A Guide for Parents, Teachers and Youth Leaders. By Cyril Bibby, M.A., M.Sc., F.L.S. (Pp. 291 7s 6d.) London: Macmillan and Co. 1944.

Sex education for the young is very much to the fore at present, and opposition to it from even the most repressed and hide-bound parents is fast disappearing. Not long ago the only education given to the curious youngster was, "When in doubt, don't," without explaining what exactly he was not to do. Any statement was backed by threats of the dire consequences of venereal disease to the body and eternal damnation to the soul. Such methods, however, in no way acted as deterrents and only degraded a subject which should be noble. The most enlightened sex education, on the other hand, will not eliminate all evil, but it will do something to improve the sexual standards of the race.

All facts are best inculcated before puberty—i.e., before 12 years old—in answer to the inevitable questions of the child, as and when they are put, not before or after. In this way he may receive them as he does other facts without emotional bias or prejudice. The author thinks that the teacher, being less emotionally involved, is the best person to give sex education, but others must do their part. In the early years of childhood it is very important that parents should adopt an unemotional attitude towards feeding, excretion, infantile masturbation, and nudity. The chapter on the school curriculum is good, for it shows how all subjects may contribute to sex education, provided a sense of proportion is maintained. The various sex problems which arise in schools are sensibly discussed, such as the emotional changes of adolescence and aggressiveness while menstruation, night emissions, and masturbation are adequately dealt with. The author notes that many sex-directed activities are not sex-motivated. He points out how theoretical is the idea of sex sublimation, and how seldom is it a really practical and efficient solution. There is a good selection of questions asked by children and young people, and a final chapter on educating the educators. Appendices include a tabulated scheme for sex education, specimen lectures, and a guide to further reading.

This is a practical, useful book, thoroughly to be recommended to all who are concerned with the future welfare of the race.

Notes on Books

Myself and My Enemies. by SAMUEL LOWY, M.D., is published by Kegan Paul, Trench, Trubner and Co. The author is a psychoanalyst who has spent the war period in England. His work on neurotics in several European countries has convinced him that the ills of society are analogous to the ills of his neurotic patients. The innate impulses of hate and aggression cannot be denied, but should be so far as possible controlled and directed into desirable channels. More understanding, more knowledge, will help, as will greater opportunities for the enjoyment of beauty and a wider satisfaction in life, with a freedom from anxiety over the

basic necessities for existence. The author does not think that these things can be left to individuals, but that the State must take the initiative in regulating human relationships. While some State regulation of the interactions of employers and workmen would be acceptable to most, many people would jib at the establishment of a Ministerial Department to regulate the inner life of families in the interests of health and happiness, however theoretically desirable this might seem to be in most cases. The chapter on sexuality in its cultural and social aspects is good, and the whole book is distinctly interesting, though, as the author himself admits, no specific concrete proposals are ventured upon.

Salts and their Reactions, by LEONARD DOBBIN and JOHN E. MACKENZIE (Edinburgh: E. and S. Livingstone; 8s. 6d.), is an introduction to chemistry presented in a form which at one time was more common than it is to-day. This form of presentation has the particular merit that the building of knowledge is begun on a foundation already familiar to the student in the facts of everyday life. This is not to say that the scheme of instruction is archaic; it is a scheme which leads in a direct ascent to the most modern considerations and treatment of chemical science. The book does not take the student far beyond the requirements of first examinations, but, providing as it does the directions for a well-selected series of practical experiments, it will prove to be a very useful accessory to the preparatory lectures for entrance examinations.

Preparations and Appliances

A USEFUL ADDITION TO THE CLAUSEN HARNESS

Dr. J. MORLAND SMITH, D.A., writes from Stoke Mandeville Hospital, Aylesbury:

A great disadvantage of the Clausen harness is that it fails to support the jaw; in fact, if applied firmly, it often depresses the jaw, causing respiratory obstruction even in the presence of an oral airway. Descriptions of gadgets for elevating the mandible have appeared in the literature from time to time, but I have not yet noticed any mention of the very simple method I am about to describe.

After a three-strapped harness has been loosely applied, a wooden tongue-depressor is placed transversely under the chin, and the two lower straps are stretched to pass over the ends of this depressor (see photograph). If the harness is likely

to be on for any length of time, it is wise to pad the spatula by wrapping a gauze dressing round it, and perhaps to alter its position occasionally. Apart from raising the jaw, the spatula spreads the lower straps, preventing pressure on the facial nerves. If the corrugated tubes and connexion are arranged to lie over the forehead in the mid-line, they do not tend to pull the head to one side but to maintain it in extension.

I have used this device with the harness regularly since 1940, and have found it most helpful, especially for giving pentothal with nitrous oxide and oxygen. Unfortunately, patients are met with whose airway cannot be adequately maintained by this method, despite alteration in pillows and type of artificial airway. I assume that these odd cases would present equal difficulty with most of the other types of jaw support.

distinction has not always been made between these two groups of post-mortem findings. As a consequence general pathological changes such as visceral congestion and capillary haemorrhages have often been invested with the significance of special pathological changes. In this way asphyxia has come to be regarded as a pathological entity.

It is suggested that a classification of deaths of medico-legal importance based upon the concept that tissue anoxia, however induced, leads to circulatory failure and death would be more in keeping with current views in applied physiology and pathology.

The Mechanism of Death

The cessation of the vital functions depends upon the production of tissue anoxia. This anoxia may be brought about in four different ways. It may be caused:

- (A) By defective oxygenation of the blood in the lungs—*anoxic anoxia*.
- (B) By a reduced oxygen-carrying capacity of the blood—*anaemic anoxia*.
- (C) By a depression of the oxidative processes in the tissues—*histotoxic anoxia*.
- (D) By an inefficient circulation of the blood through the tissues—*stagnant anoxia*.

All these types of anoxia produce circulatory failure, and this failure may lead to death.

The accompanying diagram, which has been adapted from the work of Moon (1938), shows clearly the method by which these conditions produce circulatory failure. It illustrates how the different types of anoxia give rise to the same vicious circle and how this circle operates to maintain the circulatory failure once it has been produced.

In all deaths the *initial* development of the tissue anoxia depends upon one or other of the mechanisms given under (A), (B), (C), or (D). The special position of haemorrhage—of importance in deaths from incised wounds and criminal abortion—has been indicated by Moon.

Deaths of medico-legal importance may be classified for practical purposes by the way in which the tissue anoxia is initiated.

A Classification of Deaths of Medico-legal Importance

(A) Deaths from Anoxic Anoxia:

1. (a) From an obstruction to the passage of air into the respiratory tract—e.g., suffocation, smothering, and overlying; (b) from an obstruction to the passage of air down the respiratory tract—e.g., drowning, choking by foreign body impaction, throttling, strangulation, and hanging; (c) from an external compression on the chest and the abdominal walls—e.g., from falls of earth.
2. From a primary cessation of respiratory movements—respiratory failure—e.g., narcotic poisoning and rapid deaths from electrical injuries.

3. From breathing in vitiated atmospheres. These deaths are usually caused by the displacement of the atmospheric air by carbon dioxide or inert gases—e.g., they occur from exposure to "black-damp" or "fire-damp" in mines and from exposure to the fumes in wells and vats.

(B) Deaths from Anaemic Anoxia:

This form of death occurs characteristically in acute carbon monoxide poisoning. It is also seen in poisoning by nitrites, chlorates, and coal-tar derivatives (Van Liere, 1942).

(C) Deaths from Histotoxic Anoxia:

This form of death is seen in acute cyanide poisoning.

(D) Deaths from Stagnant Anoxia:

This form of death is seen in traumatic shock in which capillary atony leads directly to inefficient circulation of the blood through the tissues. Deaths from burns, heat-stroke, acute irritant or corrosive poisoning, venom poisoning, and delayed deaths from electrical injuries may all be classified in this group.

The Basic Pathological Changes of Circulatory Failure

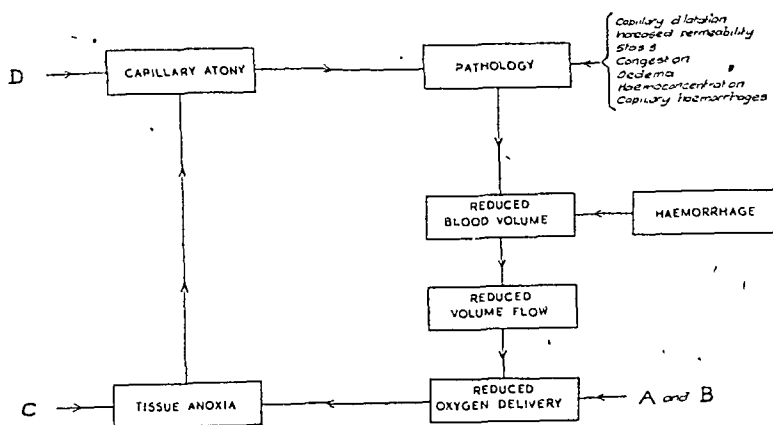

As tissue anoxia, however induced, leads to circulatory failure, the pathological changes associated with this failure are fundamentally similar in all forms of death. According to Moon the basic pathological changes of circulatory failure are: (1) Diffuse congestion of all the viscera. (2) Diffuse congestion of the mucous and serous membranes of the body. (3) Capillary haemorrhages in the viscera and tissues, and in the mucous and serous membranes. (4) Oedema of the viscera and tissues, with effusions into the serous cavities. Oedema is most commonly found in those forms of death in which the circulatory failure develops slowly.

Capillary haemorrhages in the pleura (the so-called Tardieu spots) have been observed in all the forms of death which have been included in the classification. They have no significance as a specific pathological change.

The basic pathological changes of circulatory failure are present in varying degree in all forms of death.

It has been suggested by Moon that the intensity of the congestive changes of circulatory failure may depend upon the rapidity of the death. It is difficult to correlate the degree of visceral congestion with the rapidity of the death, as it is exceptional to obtain reliable clinical evidence of the mechanism of death.

In 1941 I attempted to study this problem in relation to the post-mortem findings in a series of 41 anaesthetic deaths, all the patients were under observation at the time of their collapse. Unfortunately, reliable clinical data relating to the mechanism of the collapse could not be obtained from many of the case records. Such data were available in some cases. The conclusion drawn from the limited series of cases studied was that the relative absence of visceral congestion in deaths arising from sudden primary cardiac failure supported the view that the degree of visceral congestion is relatively less in rapid deaths as compared with deaths occurring more slowly.

The relationship of the various forms of anoxia to circulatory failure—Adapted from Moon (1938)

Asphyxia as a Pathological Entity

The term "asphyxia" is sometimes used synonymously with "anoxia." Etymologically the word means "pulselessness," and there is little reference to the term in modern works on applied physiology (Best and Taylor, 1943; Samson Wright, 1940). It would appear to be an undesirable term from the strictly physiological point of view, but it is used extensively in the practice of forensic medicine because of its convenience. It has been shown, however, that there are no qualitative differences in the general pathological changes in all deaths of medico-legal importance, asphyxia cannot be regarded as a distinct pathological entity which is recognizable on the basis of morbid anatomy. It is never justifiable, therefore, to certify that a deceased person has died of asphyxia if this opinion is based only upon a finding of visceral congestion and capillary haemorrhages.

The records of certain criminal trials in South Africa have shown that penalties, including a death sentence, have been inflicted where medical testimony, based upon the view that asphyxia is a pathological entity, has been a major factor in securing the convictions. These cases have arisen more specifically in instances of alleged suffocation, throttling, or strangulation where external evidence of injury could not be observed because of putrefactive changes or the burning of the body. It is felt, therefore, that a re-orientation of our approach to deaths of medico-legal importance, in accordance with

B.D.H. MALE SEX HORMONES

METHYL-TESTOSTERONE B.D.H. *for oral administration*

TESTOSTERONE PROPIONATE B.D.H. *for intramuscular injection*

Whenever androgen therapy is indicated the use of Testosterone Propionate B.D.H. by injection is the treatment of choice, preferably supplemented by the oral administration of Methyl-testosterone B.D.H.

Indications for androgen therapy are eunuchoidism and genital infantilism in the male, impotence and loss of libido and the syndrome of the male climacteric. Androgens may be found helpful in counteracting some of the general senile and degenerative changes associated with premature ageing, as well as the prostatic hypertrophy more characteristic of the true syndrome of the male climacteric and of which disturbances of micturition may be the premonitory signs.

current views on applied physiology and pathology, would be less likely to lead to any miscarriage of justice

Summary

A classification of deaths of medico legal importance has been suggested. This classification is based upon the concept that tissue noxia, however induced, leads to circulatory failure and death. Such a classification is considered to be more in keeping with current views in applied physiology and pathology.

It is emphasized that in the description of post mortem findings for medico-legal purposes a clear distinction should be drawn between the basic pathological changes of circulatory failure and the special pathological changes characteristic of the particular type of death under consideration. Attention is directed to the fact that there are no qualitative differences in the basic pathological changes found in the different types of death.

Because of its convenience the term "asphyxia" is used extensively in the practice of forensic medicine. It is pointed out, however, that as asphyxia does not constitute a pathological entity it cannot be clearly recognized on the basis of morbid anatomical observations alone.

This paper is published with the kind permission of Prof. W. F. Rhodes of the University of Capetown. I would also like to thank my colleague, Dr. H. A. Shapiro, for his helpful critical interest in this subject.

SPECIFIC SERUM THERAPY IN TYPHOID FEVER

BY

A. E. HODGSON, M.D. Ed., D.P.H. Camb.

Medical Superintendent, City Hospital, Fazakerley, Liverpool

In normal times typhoid fever is relatively a rare disease, thanks to the forward strides in public health and bacteriology which have been made in the past half century, and it is only when as a result of some unforeseen incident the disease assumes epidemic incidence that it attracts special attention. In the circumstances of war, however, opportunities for its appearance and spread are multiplied. Prophylactic measures go a long way in the protection of the individual and the mass in a modern army, and a supervised hygienic routine assists in averting the spread of infection. A very different state of affairs may be encountered when the present active warfare has ended and a continent in which for five years all the decencies and amenities of living have been disrupted presents itself, and infectious disease in the released peoples might constitute a major obstacle in the return to order. Among these infections the typhoid group of fevers may play an important part. Mass schemes must cater for housing, water, food, and the like, and inoculation will help in personal protection. "Inoculation," it must nevertheless be remembered, will not protect everyone to whom it is applied—a fact recognized by all who have studied and practised it. In our own forces, so splendidly "served" on the medical side, there have occurred a certain percentage of failures to confer complete immunity to the particular disease against which defensive steps have been taken. In an article entitled "Military Medicine in a Middle East," Lieut.-Col. (now Brigadier) E. Bulmer (1943), under the subheading "Enteric Group," says: "The 24 cases include typhoid paratyphoid, and clinical typhoid fever, without laboratory confirmation. The low incidence is the result of the satisfactory state of the troops with respect to inoculation, but have been impressed with the severity of the cases due to *act. typhosum*, inoculation did not seem to have modified the course of the disease once it was contracted. The mortality rate of 25% would be much higher if only cases of typhoid fever were considered. The disease remains uninfluenced by treatment but good nursing, and the sulphonamide group ineffectual."

Realizing that this case incidence, indubitably low though it is, is met with in a body of men so efficiently inoculated as are our troops, the potential incidence which might be encountered in the circumstances of starvation and disorganization in the immediate post-war Europe presents vast possibilities.

Hitherto medical treatment in the typhoid group has been mainly "general" and in a sense fortuitous and empirical success resulting almost entirely from good nursing, as most clinicians will admit. In typhoid fever, but not in the paratyphoids, there is now at hand a potent therapeutic serum to which, in my view, too little general attention has been drawn. The work of Felix and his colleagues at the Lister Institute made possible the elaboration of his "Vi+O" anti-typhoid serum in which, put briefly, two antibodies are effectively combined, the "Vi" element conferring protection by suppressing the multiplication of virulent strains of *Bact. typhosum* and the "O" antibody by neutralizing the endotoxin of that organism. Clinical trials of the new anti-typhoid serum have been reported from Palestine (Felix, 1935), Ireland (McSweeney, 1935-1937), China (Robertson and Yu, 1936), England (Cookson and Facey, 1937), South Africa (Pijper and Crocker, 1939), Malaya (Landor, 1941), and the findings point definitely to its high therapeutic value in particular in toxæmic patients. This serum has been used in the City Hospital, Fazakerley, since the beginning of 1938, and in that period 57 cases of typhoid fever have been admitted. Seven of these patients died, four deaths occurring within 80 hours of arrival at hospital. Twenty of the patients (of whom 4 died) were seaborne. These cases disembarked at the port are in the main of severe type having been ill for varying periods at sea in circumstances in which except in the largest liners, medical and nursing facilities of a standard available in a modern hospital ashore are not readily to hand. Those patients who on admission showed toxic symptoms—undue general prostration, hyperpyrexia, threatened delirium, coma or typhoid state, or complications such as hæmorrhage or pneumonia—numbering 25 in all received serum. Classified according to severity they were

Very severe	12 (4 deaths)
Severe	9 (2)
Moderately severe	4

Seaborne patients contributed 14 of the 25 serum cases and four of the six deaths, these latter being due to pneumonia (3), hæmorrhage (2) and toxæmia (1). The one death in the non-serum group was the result of old standing endocarditis in an elderly patient. The cases not receiving serum are, of course, not to be regarded as "controls," but rather as mild infections for which anxiety was not specially justified. All the patients were civilians who had not been inoculated with TAB vaccine, and the clinical diagnosis was in each instance confirmed by bacteriological or serological examinations.

Though the number of cases reviewed in the series is not large and does not permit of assertive conclusions, the effects of serum treatment were manifest in three ways.

(a) Conditions due to direct toxæmia, excluding hyperpyrexia, abated rapidly, obvious improvement appearing often within 48 hours and continuing to be sustained, with coincident decrease in signs and increase of relative strength and well being. Six of the very severe cases were of the type for which, in other times, but little hope of recovery could have been entertained, they responded with surprising and almost dramatic promptness.

(b) Hyperpyrexia was not affected in so quick a manner, a maintained fall in temperature taking some days and continuing as a moderately steep lysis.

(c) Incidental complications such as intestinal hæmorrhage or pneumonia, already present when the patient came under treatment did not seem to be influenced by the serum in any way. It was observed, however, that such conditions did not arise in the later course of the disease in those subjects to whom serum had been given in the initial and toxic phase.

The serum is issued in 33-cm phials (Lister Institute), and injection of the contents of one phial intramuscularly (buttock) on three successive days, beginning at the earliest available moment, was routine. In the very bad cases an initial dose of 66 ccm was given. This may seem a large amount for one intramuscular injection, but if the serum and the syringe have been previously warmed and kept in water at blood heat

calls it, "normal procedure," tends to take first place. I know of one hospital of nearly 1,000 beds, which comes under the Kent County Council. Their committee meets once a month; their "decisions" have to go to Maidstone, 40 miles away, for confirmation by a committee which meets once every three months.

In a hospital run by responsible people the sense of frustration caused by the delay in taking decisions has to be experienced to be believed. In a voluntary hospital, the medical officer in charge can and does give quick decisions over anything which may affect the welfare of the patient if the decision is a big one I understand that, in voluntary hospitals, the house committee meets once a week.

Directly a doctor becomes an administrator it is not, in the nature of things, possible for him to keep up to date to the same degree as a consultant.

And, forsooth, Dr. Ponder takes exception to my asking the advice of the tuberculosis officer on the spot, because he is—"tell it not in Gath"—a subordinate official and is not in a position to speak on the council's policy.

Of course no one realizes better than I the difficulties of wartime, but instances are still coming to me of persons suffering from tuberculosis who are compelled to live in their homes, and, in the opinion of one tuberculosis expert, one "free" case affects on the average eight or nine others. The vicious circle now being created will take ten or twelve years to break down. Of course this is a national problem, but it is my duty to bring to the notice of the authorities the sufferings and disabilities of my constituents, and I shall continue to do so, regardless of personalities. It is interesting to note that Dr. Ponder thought the matter sufficiently worth while to write to the *British Medical Journal*. *Qui s'excuse, s'accuse*

Through the "Fighting Fund for Freedom" (1, Dover Street, W.1), of which I am chairman, we are doing all we can to educate the voters of this country against the mortal danger of State control, of which an outstanding example is the medical White Paper recently issued by the Government, and in this nation-wide movement we should welcome the help and co-operation, already strongly in evidence, of doctors and nurses.—I am, etc.,

Knockholt, Kent.

WALDRON SMITHERS.

The Young Married Doctor

SIR.—Your correspondents Tom Barns and "Y.M.D." (Sept. 23 and Oct. 14) have stated admirably the case for the recently qualified man who wishes to marry, and it is not too soon. For such a man general practice offers a solution—hard work, a home, and a living wage for two, which is what a young man wants at the start of his career. Many men enter successfully and efficiently this branch of medicine, for the practice of which it has been truly said that "no doctor is too good." There are others, however, who feel that they must continue their hospital work, with a view either to broadening their general experience or to specializing. Marriage completely and effectively blocks this prospect in the majority of cases, and such a position is most unsatisfactory and quite unnecessary. All too often the attitude adopted by those in responsible positions is unreasonable. It is usually twofold: first, that, as in other professions, a man must wait and work until he can afford to marry; and, secondly, that for some indefinite reason it is more difficult for a young husband than a young bachelor to make a success of hospital work. Neither of these views, though they appear superficially sound, bears careful scrutiny. With regard to the first, at 25 many men have waited long enough and worked hard enough to entitle them to the privilege and responsibility of marriage by the standards of other professions. That resident's pay and hospital rules preclude this is not the resident's fault, and, as "Y.M.D." points out, the reform would be simple and comparatively inexpensive.

It is more difficult to understand the origin of the second fallacious view, but I think it probably springs from the assumption that the work of a married man, working in hospital, will inevitably suffer from his anxiety to "down tools" and get home at the earliest possible moment. This, of course, is an extremely ill-conceived idea; a married man keen enough to aim at the highest technical knowledge via long years of

study is no more likely to neglect his work than his bachelor colleague (whose leisure hours are not always, as many believe, spent with reference books, histological preparations, and case sheets).

The problem is probably not one which is exercising the minds of those shaping the future of the medical world, and this is partly understandable. It must, however, be recognized that it exists as a problem to many, whose numbers are increasing every year. It is encouraging that the subject has been raised, let us hope that it will not sink out of sight again before something constructive has been done about it.—I am, etc.,

"MARRIED DOCTOR."

Obituary

E. FRETSON SKINNER, M.A., M.D., F.R.C.P.

The life of Edward Fretson Skinner, senior physician to the Royal Hospital, Sheffield, ended abruptly on Nov. 28. An hour before his death, after the last ward round, he had a severe attack of angina. It passed off. Though advised to remain and rest he insisted on going to his consulting rooms to see a child. It was there he died.

Dr. Skinner was born in Sheffield 64 years ago. His ancestors have been doctors for several generations, his father and grandfather having been practitioners in Sheffield before him, and the former was for a number of years lecturer in osteology in the Sheffield Medical School. His uncle was also a doctor, and his brother, who died last year, conducted a very large general practice in the city for many years. He was educated at the Wesley College, Sheffield, and proceeded to Cambridge in 1899. He took up rowing with enthusiasm and rapidly became a marked man. He began to train with the Cambridge crew for the boat race, but had to drop out on account of illness. After graduating he studied medicine at the Sheffield Medical School and obtained the Conjoint Diploma in 1906. In 1907 he took the Cambridge M.B. and in 1909 the M.R.C.P. (Lond.). In 1922 he was elected to the Fellowship of the Royal College of Physicians and in 1935 he took his Doctorate in Medicine.

After doing various house appointments at the Sheffield Royal Hospital he was elected to the staff to take charge of the skin department in 1911. At this period he studied for a time in Paris under Sabouraud. In 1919 he was made assistant physician to the hospital, becoming full physician in 1931. He continued to serve the hospital with great distinction to the day he died. He served in the last war in France, and after being invalided home was attached to the Wharfedale War Hospital in Sheffield, the same hospital where, during the last five years, he has been director of the centre for psychoneuroses under the E.M.S. He lectured in psychological medicine in the University and presented to his students a clear outline of basic principles which he published in a useful little book, *An Introduction to Medical Psychology*. He possessed a profound knowledge of folk-lore and kindred subjects. He wrote a number of brilliant papers on totemism, witchcraft, etc., and he loved to delve into the habits and customs of ancient man.

His interests in medicine were wide. Dermatology had led him to the study of syphilis, syphilis to neurology, and then on to psychological medicine. It was here that his powers were to be fully extended. It was relatively late in life that he turned to this branch of medicine, and his signal success in it was due not only to the man with exceptional natural gifts meeting opportunity but also to the broad and secure foundation in general medicine that had been well and truly laid during many years of hospital and consulting practice. His greatest interest was the development of a psychiatric department as part of a general hospital service. In fact only a week before his untimely death he submitted to the medical staff plans for its furtherance. Already there were at work a neurologist and neurosurgeon and himself forming the nucleus of such a unit. His colleagues will endeavour to promote the fulfilment of his schemes.

Dr. Skinner was a man of great nobility of character. He was absolutely without any pretentiousness or ostentation of learning, yet he exerted an immense influence on all who were brought in close association with him. He was a psychologist whose success in dealing with the aberrations of the human mind and conduct was the outcome of a deep understanding and sympathy with human weakness and misfortune. His kindness and sympathy were felt by all who came in contact with him, and none could doubt his absolute

very little discomfort, and that of a transient sort only, is caused, and absorption quickly takes place. As experience in serotherapy in other diseases bears out, the generous dose of serum, especially if given early, brings a readier and more complete response than do smaller and repeated amounts.

All the patients except five in due time had an urticarial serum rash of variable intensity—a not unexpected event, as this serum is not of the “refined” type. In my personal view a simple serum rash alone is not a wholly ill-starred happening. Temporary and varying irritation is inevitable, but I have noticed in other diseases in which serum is used that, in certain patients who hitherto have seemed to be hanging fire, after the urticaria has come and gone improvement appears to be stimulated and accelerated, owing possibly, I have thought, to the ensuing leucocytosis and its added defensive mechanism—a condition to be desired in the leucopenic state of a typhoid fever patient.

I would add that while serum in typhoid fever seems to possess undoubtedly high value, its use does not in any sense minimize the prime importance of efficient nursing attention as an aid to the patient's recovery.

Summary

Clinical results following the use of Felix's “Vi+C” anti-typhoid serum are described. Its efficacy appears to be prompt and very satisfactory in those states due to pure toxæmia. Hyperpyrexia is diminished in time, but this change is not so rapidly brought about. Complications such as pneumonia and hæmorrhage, when present before the start of serum treatment, do not seem to be mitigated.

I am indebted to Dr. W. M. Frazer, Medical Officer of Health, City and Port of Liverpool, for permission to publish these notes.

Medical Memoranda

Prophylactic Penicillin

After a recent “incident,” many air-raid casualties were admitted to a hospital, including many with the usual grossly lacerated and contaminated wounds. As reports of the value of penicillin in preventing infection in battle casualties have been so favourable, five million units were speedily obtained by special messenger. Patients with more serious wounds were given 15,000 units (2 c.cm.) four-hourly by intramuscular injection, and, contrary to some reports, very few complained of the injections causing pain.* Previous experience of similar wounds led one to expect that infection of many of them was inevitable, even with the help of sulphonamides, but the absence of an inflammation in cases under penicillin control was astonishing.

Careful and thorough excision of a recent wound is, of course, the ideal procedure, but many of these cases, despite blood and plasma infusions, were in no condition to stand a time-consuming operation. In any case, some of the wounds were too deep and extensive for efficient débridement. The following is a typical case.

ILLUSTRATIVE CASE

A man aged 63, severely shocked, with multiple injuries, the most serious being a deep lacerated wound of the left buttock, from which blood was still trickling. This wound was plugged with gauze, and three hours later, after he had received two pints of blood and a pint of plasma, he was taken to the theatre. Exploration of the wound revealed extensive laceration of the gluteal muscles and comminution of the innominate bone in the region of the sciatic notch. From beneath the bony fragments a steady stream of arterial blood was escaping, presumably from the gluteal artery. As the condition of the patient precluded an extensive dissection, to expose the torn vessel, efforts were made to seize it with forceps inserted beneath the bone, in the hope that diathermy applied to the forceps would thrombose the vessel. In any case, it was intended to leave the forceps *in situ* for a few days. However, efforts to seize the artery were unsuccessful, and, as the patient's condition was deteriorating, all that could be done was to plug the wound

* When time and facilities permit, it is probably better to give penicillin by continuous intramuscular or sternal drip. One hundred thousands units a day sustains an adequate concentration of penicillin in the circulation.

with gauze moistened with flavine and to excise rapidly some of the damaged muscle. The first injection of penicillin was administered about four hours later, and subsequently at four-hourly intervals. It was anticipated that such an inadequately excised wound, in a very unfavourable situation, would become infected; therefore three days later the gauze was removed under general anaesthesia. To one's surprise and gratification there was no trace of infection—no redness of the skin, induration of deeper structures, or any discharge other than slight exudate of serum. Unfortunately, the arterial bleeding restarted on removal of the gauze, so replugging was necessary. Had it been realized that the wound was in a perfectly clean condition it would not have been interfered with. It is now proposed to leave the gauze plug *in situ* for several days, by which time the vessel should be occluded by natural means. If it is subsequently necessary to ligate the internal iliac artery the condition of the patient should have so improved that a major operation will cause little anxiety.

It appears that the bacteriostatic action of penicillin is so efficacious that in the near future, when supplies are available, its routine administration, time and circumstances permitting, will abolish the boggy of infection from traumatic surgery.

R. J. McNEILL LOVE, M.S., F.R.C.S.

Severe Fracture-dislocation of the Spine

This case is of considerable interest, as it shows a severe degree of fracture-dislocation of the spine in which practically complete recovery from paraplegia has occurred. Furthermore, the value of early suprapubic drainage is shown, as the restoration of bladder function was complete. It is also of interest in demonstrating how the spinal cord can escape damage in the presence of severe injury to the spinal column.

CASE HISTORY

The patient, a W.A.A.F. 22 years of age, was admitted five hours after her injury. She had been riding in a transport vehicle on duty when it suddenly overturned and fell down a slope. She had immediate pain in the back, and felt weak. Also she had no power in her legs. She was taken to the nearest hospital, radiographed, and given morphine. She was then transferred.

On admission the patient was pale, with a pulse rate of 100 and blood pressure 116/75; she complained of pain in the upper back

and of pins-and-needles in both legs. She had no power in the legs and was unable to pass urine. General examination revealed the following abnormalities. The bladder was palpable 2 in. above the umbilicus. The knee-jerks, ankle-jerks, and plantar responses were absent. Abdominal reflexes were normal. There was no movement below the knees, and no movement of the left quadriceps. She could tighten her right quadriceps and slightly adduct both thighs.

Sensation was normal down to the level of the eleventh thoracic nerve supply. She was hyperaesthetic to pin-prick at the level of the twelfth thoracic nerve, and below it she had diminished sensation to pin-prick and touch on both sides; there was no sensation on the sole of the left foot and left calf. Radiographs showed a severe fracture-dislocation of the twelfth thoracic vertebra (see Fig.).

Treatment.—The patient was first treated on a sorbo mattress, which was discarded on the fifth day for a plaster bed, in which she was more comfortable in every way, as small movements on the mattress caused considerable pain. Suprapubic cystostomy was

Dr Rankin joined the Sudan Medical Service in 1927, and served in Kordofan, Blue Nile, and Northern Provinces, and as a Kamakan in the Medical Corps, Sudan Defence Force. He received the Fourth Order of the Nile in 1941. He will be remembered by all with whom he came into contact for his untiring good nature, sound judgment, and the attention he so willingly gave to every aspect of his work. His patients will recall him as a painstaking and sympathetic doctor in whom they could at all times trust. He was exceptionally gifted to the needs of the country at the present time, and his death will be most widely and deeply felt. Dr Rankin during his service did much to further the progress of medical work in the Sudan. His sympathy and human virtues endeared him to all of every nationality who came for his help, and he will long be remembered with respect and affection in all parts of the Sudan.

The funeral took place at his farm, Amajuba, Mount Prospect, Newcastle District, Natal, on Sept. 16 of Dr JOHN EDWARD BRISCOE, DSO, MC. He was born on March 29, 1866, at Austwick, Yorkshire, and was educated at Giggleswick School, and qualified MRCS, LRCP from the Leeds Medical School. He went to South Africa in 1898 and practised in Christown and Volksrust Districts, Natal, until he retired in 1926 to his farm near Mjuba. Dr Briscoe took part in the Boer War, the Zulu Rebellion, the campaign in German South West Africa, where he gained the MC, and in German West Africa, where he was twice wounded and was awarded the DSO for gallantry in the field. In 1917-18 he served in France, where he was present at the death of his only son who served with the RFC in 1914-18. He is survived by his daughter, Capt. Hylda Briscoe, SA MC, and two grandsons.

Dr JOHN FREDERICK HALLS DALLY, formerly physician to the Mount Vernon Hospital when it was a chest hospital in Hampstead, and senior physician to the St. Marylebone and Western General Dispensary, died at his house in Harley Street on Nov. 4. He was educated at Wolverhampton School, St. John's College, Cambridge, and St. Bartholomew's Hospital, taking the Conjoint diplomas in 1901 and the MA, MB, MCh degrees at Cambridge in 1903. He proceeded MD in 1907 and obtained the MRCP two years later. Before settling in practice he held a number of resident posts, including that of medical superintendent of the Royal National Hospital for Consumption, Ventnor. He was assistant physician to the National Hospital for Diseases of the Heart from 1909 to 1913 and then for three years consulting tuberculosis officer for the borough of Hampstead, and after the last war he served as chairman of a special neurological board of the Ministry of Pensions. Dr Halls Dally took an active part in the work of several medical societies in London, he had been president of the West London Medical-Chirurgical Society and edited its journal. He made a particular study of arterial pressure in man, and wrote on this and other subjects in various medical journals. His book on *High Blood Pressure and its Management* reached a third edition in 1934, and he published in 1928 *Low Blood Pressure: Its Causes and Significance*, he also contributed the section on those subjects to the *British Encyclopedia of Medical Practice*.

Dr SCOTT PURVES died suddenly at Alnwick on Nov. 18 in his 83rd year. He studied medicine at Edinburgh University, graduating MB, CM in 1883, and he obtained his MD in 1887. He went to the Alnwick Infirmary as house-surgeon in 1885 and was closely associated with that institution for a period of nearly 60 years. The welfare of the Alnwick Infirmary was his chief concern, and no one did more than he to further its interests. He was a life-long member of the British Medical Association (past chairman of the North Northumberland Division), a member of the Northumberland Insurance Committee, and a member of the local Medical War Emergency Committee. He was a conscientious and painstaking practitioner and inspired patients with confidence and assurance. To young and old he was a dearly loved friend as well as physician, and his passing leaves a gap which cannot be filled. He is survived by his widow.

Dr JULIUS LOWY, honorary chairman of the Czechoslovak Medical Association in Great Britain, and professor of occupational diseases and industrial hygiene at the University of Prague, died in London on Nov. 15 after a short illness, aged 59. After taking his MD at Prague in 1909 Lowy continued post-graduate training at St. Bartholomew's Hospital. In 1917 he was appointed lecturer at Prague University. Later he specialised in occupational diseases and industrial hygiene, publishing nearly 300 papers on the subject, including a volume entitled

The Clinic for Occupational Diseases. He was expert adviser to a number of departments of the Czechoslovak Government, a member of the Council of Social Insurance, of the State Council of Health, and representative of Czechoslovakia to the Section of Social Medicine of the International Labour Office in Geneva. An anti-Nazi, Lowy left Czechoslovakia for London after Munich, and became co-founder of the Czechoslovak Medical Association in Great Britain and of the Health Charter Movement. As a member of several committees of the Czechoslovak Government he helped to deal with problems of medical relief and health reconstruction. His modesty and devotion to his work and to his country gained him a large number of friends in Great Britain.

Dr S. B. KULKARNI, assistant medical officer, Zanzibar Government Service, died on May 3, 1944, after a short illness. He received his medical education at Sir Gopaldas Sunderdas Medical College, Bombay, and qualified in 1930. He was appointed to the post in Zanzibar in 1931. Keenly interested in his profession he endeared himself not only to his colleagues and patients, but to all who knew him, by his charm and kindness. He joined the British Medical Association in 1936 and was honorary secretary of the Zanzibar Branch at the time of his death.

The Services

Col J. S. K. Boyd, OBE, and Major-Gen. T. O. Thompson, CBE, late R.A.M.C., have been appointed Honorary Physicians to the King in succession to Major-Gen. Sir P. S. Tomlinson, KBE, CB, DSO, and J. A. Manifold, CB, DSO, late R.A.M.C. (ret.), respectively, and Major-Gen. W. C. Hartgill, OBE, MC, late R.A.M.C., has been appointed Honorary Surgeon to the King in succession to Major-Gen. O. W. McSheehy, CB, DSO, OBE, late R.A.M.C. (ret.).

Col. (local Major-Gen.) J. Walker, CBE, MC, late R.A.M.C., to be a D.D.M.S., and to be Acting Major-Gen.

Col. (Temp. Brig.) (Acting Major-Gen.) E. Phillips, CBE, DSO, MC, late R.A.M.C., to be a D.M.S., and to be Major-Gen. Capt. J. Cowan, G.B. Hirst, E.W. Moore, D.W. Moynagh, Lieut. W. A. Smurthwaite and H. Thompson, R.A.M.C., and Lieut. M. Nagi, I.A.M.C., have been awarded the MC in recognition of gallant and distinguished services in Italy.

Temp. Surg. Lieut. P. N. Holmes, R.N.V.R., has been mentioned in dispatches for good services to survivors from a merchant vessel which was sunk by enemy action.

CASUALTIES IN THE MEDICAL SERVICES

Killed—War Subs. Capt. Frederick Murray Wannman, R.A.M.C. *Killed in action in Burma*—Capt. Allan Dalgleish Gould, R.A.M.C.

Accidentally killed on active service—Major Philip McLean Gunn, R.A.M.C.

Wounded—Lieut. W. N. Coombes, War Subs. Capt. A. N. MacPhail, I. Morris, and A. B. Unwin, R.A.M.C.

Missing presumed killed—Surg. Lieut. James Robertson, R.N. *Previously reported missing, now known to be a prisoner of war*—Capt. J. H. Keesey, R.A.M.C.

DEATHS IN THE SERVICES

Major-Gen. Sir MENUS WILLIAM O'KEEFE, K.C.M.G., CB, MD, Colonel Commandant of the R.A.M.C., died on Nov. 29 at Camberley at the advanced age of 85. His father was a medical man and he was born at Mount Keefe, Newmarket, County Cork, in 1859. He was educated privately and at Queen's University, Ireland, where he took the LM in 1880 and the M.D. R.U.I. and the MCh. In 1881 he joined the A.M.S., as it then was, in time to see active service in the Egyptian campaign of 1882, and was present at the battle of Tel-el-Kebir. He next saw service on the North-West Frontier of India in the Tirah Expeditionary Force in 1897-8 and with the Mohmand campaign in 1908. In 1910 he was promoted colonel, and from 1911 to 1914 held the important post of Inspector of Medical Services, War Office, after having served for five years at the Royal Herbert Hospital, Woolwich. He was thus marked out for responsible duties during the war of 1914-18, when he went to France with the Expeditionary Force and served throughout as Deputy Director of Medical Services, Rawlinson's Fourth Army, and was mentioned in dispatches seven times. Here he did fine work in the evacuation and treatment of the sick and wounded throughout the battle of the Somme, and the improvements he made in the speedy collection and evacuation of the wounded saved many valuable lives. For these conspicuous services he was awarded the CB in 1915 and the K.C.M.G. in 1918. He also received the

TO CORRECT THE BLEEDING TENDENCY IN OBSTRUCTIVE JAUNDICE AND AMONG THE NEWBORN

● Wherever haemorrhage occurs associated with low prothrombin levels, 'Kapilon' vitamin K analogue is indicated.

Prothrombin deficiency may occur in cases of obstructive jaundice when absence of bile prevents normal absorption of vitamin K. Pre-operative injection of 'Kapilon' is being used as a routine by many surgeons as a safeguard against grave haemorrhage in such cases.

'Kapilon' is also successfully used in many intestinal disorders (e.g. intestinal obstruction, colitis, sorue) which by affecting prothrombin metabolism may be a cause of spontaneous haemorrhage.

'Kapilon,' however, has had its most dramatic successes in controlling haemorrhage among the newborn in whom the physiological reduction in prothrombin levels may descend below a safe threshold. In such cases, bleeding from the cut cord, intracranial haemorrhage following birth injury, or spontaneous haemorrhage from the bowel may have serious consequences.

'Kapilon' given to the baby at birth or to the mother before labour acts prophylactically while, given to the child at the first sign of bleeding, 'Kapilon' may stem the haemorrhage before loss of blood or extravasation brings death or irreparable damage.

PRODUCT OF THE
GLAXO LABORATORIES

KAPILON

MENAPHTHONE AND ACETOMENAPHTHONE

Ampoules 6 x 1cc. Tablets 25 and 100 Liquid ½ oz.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434

THE SAFE LAXATIVE

Constipation is probably the most frequent cause of ill-health, and it is the concern of those who tend the sick, to relieve their patients from this disorder.

In this connection, 'California Syrup of Figs' perfectly meets the need for a safe yet efficacious aperient. Completely void of mineral or synthetic cathartics, it is corrective not purgative, and re-educates the bowel to normal function.

Its pleasant taste and simplicity of dosage makes 'California Syrup of Figs' the laxative of choice for young and old alike. It may safely be employed either in occasional constipation, or for routine use in everyday family life.

'CALIFORNIA SYRUP OF FIGS'

Contains approximately 27.8% Ext. Senn. Fol. and 27.0% Syrup Ficorum
(1 in 10) with carminative, sweetening and flavouring agents.

THE CHAS. H. PHILLIPS CHEMICAL CO., LTD., 179, ACTON VALE, LONDON, W.3.

Mr. Amery circulated a list of the members of the committee, the medical members of which are: Rai Bahadur Dr. A. C. Banerjee, Director of Public Health, United Provinces; K.B. Dr. Abdul Hamid Butt, Director of Public Health, Punjab; Dr. R. B. Chandrachud, Chief Medical Officer, Baroda State; Lieut.-Col. E. Cotter, Public Health Commissioner with the Government of India; Dr. D. Y. B. Dadhaboy, ex-President of the All-India Association of Medical Women, Bombay; Dr. J. B. Grant, Director, All-India Institute of Hygiene and Public Health, Calcutta; Dr. Mohammad Abdul Hamid, Professor of Pathology, Lucknow University; Col. J. B. Hance, Director-General, Indian Medical Service; Sir Henry Holland, C.M.S. Hospital, Quetta; Dr. H. M. Lazarus, Women's Medical Service; Diwan Bahadur Dr. A. Lakshmanaswami Mudaliar, Vice-Chancellor, University of Madras; Dr. U. B. Narayanrao, President, All-India Medical Licentiate Association; Dr. B. Vishva Nath, Member of the Medical Council of India; Major-Gen W. C. Paton, Surgeon-General, Bengal; Dr. B. C. Roy, President, Medical Council of India; Lieut.-Col B. Z. Shah, I.M.S. (ret.), Superintendent, Mental Hospital, Poona, formerly Director of Medical Services, Sind; Dr. Hemandas R. Wadhvani, Secretary of the Committee, Rao Bahadur Dr. K. C. K. E. Raja, I.M.S.

Mr. Amery also told Mr. Gallacher on the same day that the Director General of the Indian Medical Service had just completed a visit to this country and the United States of America, in which he explored means of promoting medical research in India and liaison between Indian research workers and those elsewhere. The Government of India looked forward to receiving recommendations on these subjects from the Health Survey and Development Committee under Sir Joseph Bore (of which the Director-General was a member) and had already before them valuable proposals made by the honourable Member for Cambridge University. The Famine Inquiry Commission under Sir John Woodhead had within its scope the effects of the Bengal famine in respect of malnutrition and deficiency diseases. Dr. Aikroyd, Director of the Nutritional Laboratory at Coonoor, was a member of the Commission.

Refresher Courses for Service M.O.s

Sir E. Graham-Little was informed by Mr. WILLINK on Dec. 6 that proposals have been under discussion with representatives of universities and others with the object of enabling medical officers released from the Forces who had not, before serving, become established in practice to obtain three or six months' clinical experience in hospitals under expert guidance before going into practice and also of providing short refresher courses for those who were previously general practitioners. It is intended to circulate particulars of the scheme, as soon as it has been settled, among serving medical officers.

Domestic Staff of Hospitals

In answer to Wing Cmdr James, Mr. ERNEST BEVIN said on Dec. 7 that no women domestic workers had been withdrawn from hospitals. Throughout the war hospital domestic work had been regarded as work of national importance carrying the appropriate priority. Following the report in November, 1943, of the Hetherington Committee special priority was accorded to domestic needs of hospitals. Between the granting of the special priority and Nov. 8, 1944, 38,000 women and 3,000 men had been placed as domestic workers in hospitals, sanatoria, mental institutions, and nursing homes. Wastage had continued to be heavy, with the result that, despite this large number of placements the number of domestic workers employed in hospitals during the period January to September, 1944, increased by fewer than 5,000. The special priority for hospital domestic work was being continued, and his Department would continue to make every effort to fill outstanding vacancies.

Ministry's Pamphlet on Smallpox

Mr. ALFRED EDWARDS inquired on Dec. 8 why "an out-of-date pamphlet with regard to the diagnosis of smallpox" had been circulated by the Ministry of Health. He asserted that this pamphlet did not solve difficulties which had recently arisen in regard to the diagnosis of smallpox. Mr. WILLINK replied that the pamphlet was written by an authoritative and highly competent author. Its value to those concerned in the diagnosis of smallpox was as great to-day as when it was written. He had set up a panel of consultants with special experience of smallpox whose services were available to practitioners when required.

Relief for Channel Islands

In the House of Commons on Dec. 12 Mr. HERBERT MORRISON announced that the British Government had decided to supplement the rations of the civil population of the Channel Islands by sending medicine, soap, and food parcels on the basis of those supplied to prisoners of war. The German

Government had now agreed to this procedure, and had granted a safe conduct to the ship which would convey the supplies to the islands. Final arrangements for the departure of the ship had not yet been completed, but the Government had every reason to believe she would be ready to sail within the next few days. Sir RALPH GLYN asked if a representative of the Red Cross would accompany the ship to see what arrangements would be necessary in future for medical stores. Mr. MORRISON said he would take note of that point, but he did not want to go further into detail at the moment. He had reasonable belief that the satisfactory distribution of the stores would be taken care of.

Inspection of Japanese P.O.W. Camps

On Dec. 12 Mr. R. MORRISON asked the Secretary of State for War whether the Japanese Government have recently indicated any willingness to widen the scope of inspection of prisoners' camps by the International Red Cross.

Sir JAMES GRIGG replied. The Swiss Minister at Tokio was informed, in a discussion with the Japanese Minister for Foreign Affairs at the beginning of November, that he had secured permission for camps in occupied territory to be visited by representatives of the International Red Cross Committee. The Japanese Minister for Foreign Affairs agreed to confirm this statement in writing. From a later telegram it is learned that the Japanese Foreign Office had written that the question was still being examined, but that it was thought that authorization might be given to visit camps in Singapore and Siam.

Milk for Expectant Mothers after the War—On Nov. 14 Major MARKHAM asked the Minister of Food whether, in connexion with social insurance, it proposed to continue in the post-war years the existing arrangements by which pregnant women, nursing mothers, and children up to school age could obtain essential supplies of milk and vitamins, which had contributed so effectively to their maintaining their health during the war. Mr. MARBANE said no change was contemplated in the welfare foods scheme as at present administered so long as food shortages continued and consumption of liquid milk by the general public was restricted. Consideration was being given to the best means of ensuring that the special needs of children and pregnant and nursing mothers would be met when liquid milk and other essential foods were again in ample supply.

Supply of Teats for Babies—On Nov. 7 Mrs. TATE asked the President of the Board of Trade when the promised increased supplies of teats were going to be available, and whether he was aware of the serious situation in which mothers and children were placed because of the continued shortage.

Mr. DALTON said that the weekly production of teats had now been doubled compared with the average for July and August, and was still increasing. Larger supplies were now reaching the shops. He had taken steps, in consultation with the manufacturers and distributors, to ensure that supplies were evenly distributed over the country.

Proposed New Chest Hospital at Swansea—On Nov. 14 Sir WM. JENKINS asked the Minister of Health if he was aware of the appeal made by the King Edward VII Welsh National Memorial Association to be supplied with a modern chest hospital at Swansea, covering the requirements of thoracic surgery to serve the whole of South-West Wales, and what action he was taking to meet this overdue need. Mr. WILLINK replied that he was aware that the King Edward VII Welsh National Memorial Association had under consideration the question of a new hospital at Swansea. He would be prepared to consider, in the light of prevailing conditions, any proposals which might be submitted to him by the association.

Hospital Accommodation for Repatriated P.O.W.—On Nov. 28 Lieut.-Col. THORNTON-KEVSELEY asked the Secretary of State for Scotland if he was aware that repatriated British prisoners of war who arrived in England this autumn had to be detained in hospitals in the South for many weeks because suitable hospital accommodation was not available in Scotland, and how he proposed to ensure that this would not happen in future cases. Mr. JOHNSTON said that there had not been any general difficulty about transferring to Scottish hospitals repatriated prisoners whose homes were in Scotland, though he understood that four repatriated patients suffering from tuberculosis and sent to hospitals in England could not be quickly transferred because there was a waiting-list for admission to hospital of tuberculous patients in Scotland. The particular cases which the hon. Member had in mind had not been transferred to Scotland.

High frequency Apparatus—On Dec. 5 Mr. R. MORRISON asked the Postmaster-General if he was now able to release medical radio apparatus surrendered by private persons at the outbreak of war and to permit its use by medical men. Capt. CROOKSHANK said that since July, 1942, as was announced in the Press at the time, owners of high-frequency apparatus taken into Post Office custody might apply to his Department for a permit to have it returned. It was a condition of granting a permit that a suitable screen and filter must be installed for use with the apparatus so as to limit radiation.

Notes in Brief

The rate of admissions to hospital for dysentery and kindred diseases from the British Army in India was less than 7½% of troops serving in 1943-4, compared with the pre-war annual rate of 5½%.

IMPROVED CONTROL

IN DIABETES MELLITUS

Globin Insulin (with Zinc), 'Wellcome' brand, is a clear solution with an action which is quick in onset and moderately prolonged in duration. This feature gives improved control of the blood-sugar level in many cases of diabetes, enabling them to be satisfactorily maintained on a single daily injection.

GLOBIN INSULIN

'Wellcome' (with Zinc)
Brand

Bottles of 5 c.c., 40 units per c.c., 2/6.
Bottles of 5 c.c., 80 units per c.c., 4/5.

Prompt relief *For*

HEAD COLDS & NASAL CATARRH

THE headache and fullness which result from nasal congestion may be promptly relieved by the use of 'Endrine.'

Quickly spreading over mucous surfaces, 'Endrine' gives immediate results, and has a prolonged effect. It relieves congestion, clears the nasal passages, and improves breathing.

The oily base in 'Endrine' has a soothing and protective effect on inflamed mucous surfaces.

'Endrine' Ordinary Formula: Ephedrine 0.75% w/w, Menthol 0.5%, Camphor 0.5%, Eucalyptol 0.5%, Oleum Ricini 0.35%, Light Liquid Paraffin ad qs. 100%.

'ENDRINE'

ANY QUESTIONS?

Displacement Treatment of Sinusitis

Q.—I once saw a demonstration of the "epidural displacement" technique for a heavy cold and sinusitis. Can you tell me the easiest method of carrying out this procedure? What are the indications for its use, and how efficient is it?

A.—The introduction of fluid into the nose and the production of suction can both be carried out by a simple hand apparatus. The success of this method depends upon a number of technical details, too lengthy for inclusion here. A modern textbook or Proetz's original articles should be consulted. As a method of treatment, displacement, acts by diluting masses of secretion too heavy for the cilia to move. Such cases occur mainly in the subacute stage of sinusitis, where the method is well worthy of trial. If carried out efficiently and applied only to suitable cases, a high percentage of good results can be expected.

Intolerance to Iodides

Q.—I wish to give iodides to a patient with intermittent claudication who informs me that he is unable to tolerate them. Can iodism be abolished by adding *liq. arsenicalis* to the mixture?

A.—The addition of liquor arsenicalis to a mixture of iodide will have no effect in preventing iodism. Arsenic seems to be of some value in preventing the skin manifestation of bromism, but even in this respect is by no means dependable.

Prolonged Use of Mercurial Diuretic

Q.—A man aged 35 diagnosed as suffering from adhesive pericarditis (Pick's disease) has been treated for 5 years with a mercurial diuretic to reduce the dropsy. Are there ill effects likely to be caused by such prolonged use?

A.—There has now been sufficient experience to show that mercurial diuretics can be injected once a week for 5 years or more without any harm except the rare occurrence of sensitization to the drug. There has been less experience of the ingestion of these mercurial compounds by mouth but no ill effects have been reported. The present inquiry does, however, raise one question—that is, Has operative treatment been considered for this patient, for the disease process appears to be relatively static and he might therefore be permanently relieved by surgery?

Relative Infertility

Q.—A man and wife aged 46 and 41 respectively, after 8 years of married life had a child 10 months ago which, although healthy at birth, died shortly after from infantile diarrhoea. As this is the first successful fertilization in 8 years and as the wife is 41 and most anxious to have a baby, what could be done to ensure fertilization in a couple whose past experience is not encouraging? The husband, I understand, can achieve only partial erection. Would any treatment be of help to the wife, and would, for example, the taking by her of vitamin E and progesterone heighten a possibly lowered fertility?

A.—It seems unlikely that the death of the child from infantile diarrhoea had anything to do with the alleged subfertility of the parents, especially as the child was healthy at birth. The fact that the husband can achieve only partial erection and that he was nevertheless able to effect fertilization of an ovum suggests that he is relatively impotent and that the cause of this is psychological. One would like to know whether, in support of this view, coitus occurs only infrequently, if so, attention should be directed to the husband rather than the wife, and in any case an examination of the seminal fluid should be made, as in all cases of sterility or subfertility where the wife is not obviously involved. The suggested treatment of the wife with vitamin E and progesterone is one often

applied to subfertility in the female where there is no obvious cause, and perhaps is clinically justified. Nevertheless, the administration of hormones is most successful when specific and based upon definite evidence of their complete absence or of their secretion in sub-normal quantities. Confirmation of this possibility in the case of progesterone can be obtained by diagnostic curettage in the latter half of the cycle, and by pregnandiol assay, a procedure which will come into more general use as soon as sufficient technical experience and personnel are available.

An Infant-feeding Problem

Q.—While breast-feeding my daughter, now aged 5 months, I have taken Ministry of Food orange juice regularly as the infant herself refuses it. For the first few months she had a slight erythematous rash, sometimes becoming pustular mainly over the area covered by the nappin. The pustules would clear up rapidly on application of a zinc, kaolin and boric powder. Care is taken over frequent changing of nappins and over rinsing out soap used in washing. When the orange juice was discontinued the rash was absent. When it was recommenced the rash reappeared. No pustules have so far developed. Glucose is added to the orange juice to counteract acidity. The diapers rarely become soiled, as she is "pooped" before and after feeds and are usually only damp with urine. The stools are occasionally slightly frothy. I have experienced no reaction while taking the orange juice during pregnancy (without glucose) or after parturition. The rash seems to be caused by a product of the fruit juice excreted in the urine. Are there any precautions that might be taken?

A.—It is not quite clear what is meant by the phrase "to counteract acidity," for the net effect of orange juice in metabolism is towards increasing the alkali intake. If what is meant is sourness of the juice, then it may be that in this particular instance some ingredient of the juice is passing out through the mother's milk and causing both the occasional frothy stools and the irritant urine. It is well known that with some nursing mothers their infants may be upset if the maternal diet contains sour fruit, but it is not always the case nor is it common with orange juice. On the other hand, if what is meant is mild indigestion in the mother, it is recognized that for reasons which are obscure, indigestion in the nursing mother may be associated with a similar disturbance in the infant. The simplest solution—and the answer to the final question of the query—is to change the source of vitamin C, using some other active fruit juice or purée, or tablets of ascorbic acid. Whatever the term 'acidity' is meant to indicate, it is difficult to see how glucose could have any effect upon it.

Stimulating Lactation

Q.—For every patient who needs to have lactation curtailed there are a dozen whose milk supply needs to be increased. Can this be accomplished at reasonable cost by hormone therapy?

A.—There is a hormone of the anterior pituitary—prolactin—which is believed to initiate lactation. A commercial preparation of this hormone is available. Kenny and King (*Lancet*, 1939, 2, 828) claimed good results from the use of this preparation for stimulating lactation and increasing a deficient milk supply. Stewart and Pratt (*Endocrinol.* 1939, 25, 347) were unable to confirm these results, and concluded that the preparation was ineffective for stimulating lactation in woman. It seems doubtful whether hormone treatment is likely to benefit cases where milk secretion is deficient.

Four measures for increasing a deficient milk supply can be recommended: first, a large fluid intake, at least six pints daily; secondly, a good diet, and some of the extra fluid can be taken as milk or soup; thirdly, bathing the breasts alternately with very hot and with ice-cold water half an hour before each feed; and, fourthly, massage to the breasts and exercises for the pectoralis major muscles. These last measures undoubtedly act by increasing the blood flow through the mammary tissue. Preparations of cotton seed oil have also been recommended, but their value is empirical.

Effects on Libido of Certain Operations

Q.—What are the effects on the libido of (a) oophorectomy, (b) partial salpingectomy, (c) x-ray or radium therapy?

A.—Although the ovaries, through their production of oestrogen, are primarily responsible for sex drive in female lower animals, the same is not true for women, in whom sex desire and allied emotions are largely governed by mental processes, and the ovaries play a minor part. (a) To some extent the effect depends on the age of the patient and whether she is already experienced in physical love. If we can assume the latter, then bilateral oophorectomy does not as a rule reduce libido, providing that coitus is practised regularly and contraindication of the vagina, which would cause dyspareunia, is prevented. Unilateral oophorectomy does not have any effect on libido. (b) The answer to this is, none. (c) X-ray therapy and the intra uterine application of radium, both adversely affect ovarian function, the extent and duration of the effect depending

performed by Mr. Broster, under local anaesthesia, 29 hours after the injury. On the third day sensation was improving, but there was no motor recovery. She had a slight haemoptysis and pyrexia due to injury of the lung, associated with fracture of the twelfth rib. On the fifth day open reduction was attempted, but was abandoned on account of her very poor condition, due to her injured lung. A plaster bed was made and mounted at once in the theatre. After six weeks she was moving all the muscles of her right leg and also the left toes. Up to this time attempts at open reduction were still contraindicated by her poor general condition. At the seventh week I inserted a graft, 5 in. by 1½ in., from the tibia on to the right side of the three spinous processes above the injury and to the left side of the lower three spinous processes. She was nursed for twelve weeks in a plaster bed on her face. At the eighth and ninth weeks root pains were severe and were not controlled by morphine. They have not recurred since.

Exactly six months from the injury she was able to walk unaided and without any instrument. On the same day the suprapubic catheter was finally removed as bladder function was normal. The bladder had remained uninfected throughout.

I should like to thank Mr. R. L. Broster for performing the suprapubic cystostomy and also Dr. Arthur Sunderland, Mr. Ciron and Mr. Beer for their great help in this case. Finally the patient is greatly indebted to all the nursing and physiotherapeutic staff, especially to Sister Hopney for her help and for the nursing which this difficult case required.

E. H. HAMBLY, M.B., B.S., FRCS

Surgeon E.M.S., Royal National Orthopaedic Hospital, Stanmore

Thrombocytopenic Purpura and Tooth Extraction

The following case of dental extraction in a patient with thrombocytopenic purpura may be found of interest.

CASE HISTORY

The patient, a married woman aged 27, had been treated for profuse menorrhagia when 15 years old. Several blood transfusions did not improve the girl's condition, and finally in 1933 a subtotal hysterectomy was performed to prevent her dying from blood loss.

She was first seen in the Dental Department of St. Nicholas' Hospital, Plumstead, on June 22, 1944, with a note from an outside doctor requesting dental extraction and saying that the patient was a haemophilic. She had complained of severe toothache for the last four weeks, the tooth involved being 3. There was a definite history of bleeding tendency—i.e., bruises appear after insignificant trauma, and small cuts bleed for days.

Haematological Findings—June 26, 1944. RBC 4,150,000 per c.mm., Hb 86%, C.I. 1.04, WBC 8,000 per c.mm.—polymorph neutrophils 80%, basophils 2%, lymphocytes 15%, monocytes 1%, Turk cells 2%. Stained film, normal. Platelets, too few for accurate counting, but about 4,000 per c.mm. Hess's capillary resistance test, positive, a good crop of petechiae. Coagulation time, 2½ minutes (within normal limits), bleeding time, 1½ minutes (normal 2 minutes), Prothrombin time, 19.4 seconds (within normal limits). The patient belongs to Group O, and was found to be Wassermann- and Kahn-negative.

In view of the above findings a condition of essential thrombocytopenic purpura was diagnosed.

Management of Case—The woman was admitted to hospital on July 6. The next day, at 10 a.m., blood was collected from two Group O blood donors, to supply lacking platelets; normal blood transfusion was given. Immediately afterwards, at about 10.15 a.m., a slow intravenous drip transfusion was started with the fresh blood found to be compatible. At 1 p.m. premedication, consisting of amonoan gr 1/3 and scopolamine gr 1/150, was administered. At 2.15 p.m. the patient was ready in the operating theatre, the intravenous blood drip being continued. 5 c.cm. of pentothal sodium (0.25 g.) injected into the rubber tubing of the blood-transfusion apparatus was sufficient to induce satisfactory anaesthesia. The tooth was extracted, it was carious and septic. The tooth socket was then lightly plugged with gauze impregnated in freshly prepared 1 c.cm. styphen solution. A clot in the socket was seen to form about 5 minutes after extraction. No further bleeding from the gum occurred. At 4.30 p.m. the blood transfusion was stopped. The total quantity given was 800 c.cm.

On the morning of July 8 the red cells numbered 3,140,000 per c.mm., and the haemoglobin was 100%. Stained film, normal, platelets, 82,000 per c.mm. Hess's capillary resistance test, positive but far less marked; coagulation test, 1 minute 40 seconds, bleeding time, 3 minutes.

The patient was discharged on July 9 after making a successful recovery without further blood loss. When I examined her on July 14 her condition was still satisfactory.

COMMENT

Dental extraction in a patient suffering from thrombocytopenic purpura should be considered a major medical and surgical problem. Admission to hospital or similar institution is essential, because it affords facilities for blood transfusion, general anaesthesia, and collaboration of dental surgeon, physician, and pathologist if necessary.

All haematological examinations were performed by Dr. Holman, assistant pathologist to the Lewisham Group Laboratory, Dr. A. S. H. for assistance, as the physician in charge was unavailable in connection with this case.

JAMES W. WHITE, L.D.S.Eng.

Reviews

ANAESTHETIC PRACTICE

Fundamentals of Anaesthesia: An Outline. Second edition (Pp 231 illustrated. No price given). Chicago: American Medical Association Press 1944.

The authors form the Subcommittee on Anaesthesia of the National Research Council of the U.S.A. Their names are already well known and respected in British anaesthetic circles, and this book confirms that they are men of wide clinical experience. Throughout emphasis is laid on those fundamentals of anaesthetic practice that make for safety. Barely a page but contains a pithy gem of wisdom worthy of hanging as a text in anaesthetic rooms. Two typical examples are: 'The good anaesthetist observes the whole patient not just the head', and 'Noisy breathing is obstructed breathing, but obstructed breathing may not be noisy'. The illustrations though comparatively few for an instructional book, are all helpful; the diagrammatic ones in particular drive home their lessons with force. In the section on general anaesthesia the choice of a particular agent is rightly given second place to principles and method—a point of view as yet not fully appreciated in this country. In the section on local anaesthesia, techniques of doubtful practical value, such as trans-sacral and sciatic nerve block, are included. These are hardly 'fundamental,' and by their exclusion more space could have been devoted to procedures which are of accepted utility, like regional anaesthesia for abdominal operations. Here and there geographical bias is suspected, outstanding examples occur in the description of spinal anaesthesia. Heavy nupercaine popular in this country, does not receive mention, and exception must be taken to the statement that the dosage of a spinal anaesthetic drug should be based on the weight of the patient.

The style is didactic and dogmatic—all to the good in a book of this kind. The predilection for tabulation—reminiscent of the 'synopsis' style of writing in this country—makes the reading a little difficult but does not detract from its value. Doctors who without special training, are likely to be called on to give anaesthetics will find this book a friend, the advice it gives is sound and can be followed with confidence. To the teacher of anaesthetics it should have no less an appeal, he will find in it many an aphorism that will delight and benefit his pupils. In addition it provides a concise and pithy summary of current American views on anaesthetics.

MEDICAL DISEASES OF WAR

Medical Diseases of the War. By Sir Arthur Hurst, D.M., F.R.C.P. Fourth edition (Pp 511 illustrated 21s). London: Edward Arnold and Co.

A book which attains four editions during the war has thereby proved its value and stands in little need of commendation from us. Having reviewed the third edition comparatively recently (1943 1, 321) we will confine our remarks to certain new features. Infective hepatitis is now the most important infection in the British Army, presumably due to a virus conveyed by droplet infection, sometimes by those suffering from subclinical attacks. Biopsy proves that it is a true hepatitis, the extensive necrosis found post mortem being due to subsequent autolysis. A curious feature is the ravenous appetite which may follow the initial anorexia. Stress is laid on the sensitivity of the liver to alcohol after an attack, and total abstinence for at least a year is urged, for even moderate amounts are liable to cause cirrhosis. Readers of this *Journal* are aware that Sir Arthur Hurst had very definite views on sciatica, and will not be surprised that the chapter on this subject has been written in his best controversial style. The introduction of sulphaguanidine has changed the treatment of bacillary dysentery, and attention is called to the fact that the intestinal lesions are not caused by the local action of the bacilli but by their toxins absorbed by the colon. Therefore the former treatment was to wash these out by salines as quickly as possible, and to neutralize them after absorption by antidyenteric serum. Now, however, as one can prevent the formation of toxins by destruction of the bacilli by chemotherapy, salines are unnecessary, though serum is still useful.

on sex and desire. Again any reduction in sex desire is absent or minimal.

The above comments apply only to the direct effects of the operations in question, but, in view of the dominant part played by the central nervous system and the woman's outlook, it should be kept in mind that the suppression of ovarian function and the cessation of menstruation may, by a psychological rather than an endocrinological mechanism, result in diminished libido. This is because so many women wrongly believe that a surgical or even a natural menopause inevitably means a loss of interest in sex. If they expect such, then it is likely to occur. If, however, this idea is refuted, and a woman is assured that she can expect to continue a normal sex life, then it is exceptional for a loss of libido to occur. Indeed, there are cases in which sex desire appears to be increased by oophorectomy, but, again, the basis for this is a psychological one. The continuance of menstruation and the absence of climacteric symptoms make it rare for bilateral partial salpingectomy to have psychological effects. Nevertheless it must be conceded that in some women the consciousness of their sterility might affect libido—either increasing it or decreasing it, according to their point of view.

Penicillin and Arsenic

Q.—In Legge's "Handbook on Industrial Medicine" (1934 p 80) it is stated that certain moulds, notably *Penicillium brevicaulis*, can split up arsenic compounds in the form of a gas and so cause arsenical poisoning in persons living in rooms the wallpaper of which contains arsenic. Is it possible that a person with arsenic in the body might be adversely affected by penicillin and if so, should not this question be worked out?

A.—It is presumably meant that penicillin may conceivably react with an organic arsenical compound administered, for instance, for the treatment of syphilis, and so liberate arsenic in a more toxic form. If so, the short answer to this question is that penicillin and mapharsen have been administered together in the treatment of syphilis (J E Moore *et al*, *J Amer med Ass* 1944, 126, 67) with no untoward effects. In any case it is a far cry from the liberation of volatile arsenic from an inorganic compound by a living penicillium of different species from *P. notatum* to the reaction of penicillin with an organic compound of arsenic. The former effect is presumably due to enzyme action, and it is scarcely conceivable that anything but the living mould could bring it about.

INCOME TAX

Employment of Wife

W D inquires how much salary is payable to a wife without her having to pay income tax thereon?

. £89. A wife receiving that amount for 1944-5 is entitled to £9 earned income relief and £80 wife's special earned income allowance, leaving a net liability of £89-£89, i.e., nil.

Share of Fees Payable to Executrix

R R Is the half-share payable to the executrix for twelve months from the date of death liable to tax?

. Yes. It is part of the total profits assessable on the firm. It does not carry earned income relief as it is not earned immediately from the carrying on by an active partner of his share of the professional work.

Employment: Home Expenses

J C has been working as a whole-time assistant. She has a child aged 2 years, and in order to be free to perform whole-time duty has to employ someone to look after the child. That expense has been refused by the inspector of taxes, with the result that the tax payable on net earnings is excessive.

. The inspector's contention is presumably founded on an old judicial decision. The case dealt with a claim by a married schoolmistress for part of the expense of keeping a domestic servant. In effect the court held that whether the expense was "necessary" or not, it was not incurred "in the performance of the duties" of the employment. The application of this decision to the facts in J C's case seems justifiable in law, though the result certainly creates a hardship in present conditions.

Damage by Bombs

A R was bombed in 1940 and (in another house) also in 1944. What claims can he make for income-tax deductions?

. No claim can be made for damage to private belongings, but claims can be made in respect of professional equipment in so far as the expense is not covered by insurance or War Damage Compensation. The claims will be based on the cost of removing and/or replacing items of professional furniture and equipment, including the car if that is being dealt with by replacement cost allowance and not by depreciation allowance. Costs of removal, including agents' fees, etc., are also allowable.

LETTERS, NOTES, ETC.

Rocking Movements in Sleep

S R D writes. The question in the *Journal* of Dec 2, 1944, of the boy of 3 who rocks in the knee-elbow position when half asleep attracted my attention, and the following personal observation may interest the inquirer. I have three children, all boys and of 1½, 4½, and 5½; they each developed this characteristic habit about the age of 1 year, and the youngest still practises it regularly. They rock on knees and hands rather than elbows, and in so doing put their head on the cot so forcibly that the noise can be heard throughout the house. Yet the impact does not appear to wake them to full consciousness. The rhythmical movement, always in the same position, occurs when they are in process of going to sleep, and in that it appears to help rather than hinder. They do particularly when sleep is disturbed either by noise, a full bladder, or by the child getting uncovered and cold. The habit appeared unusual that I have inquired among friends and relatives, but have not previously heard of any other child who had it, except my eldest brother's two boys, who apparently exhibited the same manner in childhood. There can hardly be any question of one child imitating another because the cousins have never met, and, as regards my own boys, the youngest at any rate has never slept in the same room as the other two. Another of my brothers has two children, both girls, and neither has been subject to this rocking movement; neither have my sister's children (1 boy and 2 girls). However, I sometimes wonder if it is a familial trait, and also whether it appears in boys rather than in girls. As regards treatment we have done nothing except to see so far as possible that the child is kept warm and to prevent bruising of the head by padding the cot end. We have never drawn the child's attention to the habit, and have waited in the expectation that it would "grow out of it." So far our attitude appears to have been justified. Already the two eldest boys have almost ceased the practice. But I should add that one of my nephews continued it until about 13 years of age. For fear of ridicule he made himself give it up on going to a boarding school, but even then, during holidays, would occasionally indulge, and he described it as giving rise to a pleasurable and soothing sensation—conducive to sleep. In none of the instances quoted does there appear to have been any question of masturbation. All five boys are normally developed and are physically and mentally healthy, and, we flatter ourselves, are at least of average intelligence. I hope you will not mind if I sign this very personal note with a pseudonym.

Skin Protection for Fractured Lower Limbs

Dr E W BEDFORD-TURNER writes from Southlands Hospital, Shoreham-by-Sea. In view of the increased use of skin extension in fractures of the lower limbs perhaps the following hint might be of use. A "viscopaste" bandage (Unna's paste type) is applied to the whole of the fractured limb from the foot to nearly the top of the thigh. The extension strapping is then applied directly on to the viscopaste bandage and is kept in place by another "viscopaste" bandage applied from just above the ankle to the upper level of the extension strapping. I have used this method with great success in old patients and in those whose skins are sensitive to extension strapping. It can also be used where the skin is already damaged or where the fracture is complicated by varicose veins.

Mental Hospital Doctors' Pay

"X Y Z" writes. "A M O" in his letter (Oct 28, p 5) refers to the salary scales of A M O's in mental hospitals antiquated. I agree that immediate revision of the scales is indicated. Medical superintendents are generously paid, provided with palatial residences, and receive emoluments that defy evaluation. The poor A M O is forgotten. It is he who actually administers the complicated modern psychiatric methods of treatment, and it is expected of him to supplement his qualifications with a DPM. Surely his remuneration sadly needs readjustment on lines comparable to those of the admirable Rushcliffe awards.

Horticultural Mishap

Dr A M MORRICE (Southampton) writes. The following case may be considered worthy of recording owing to its unusual features. On Sept 23 an old lady of 76 came to see me with the history that she had been gardening that afternoon and had noticed a number of garden snails about. When she was having her tea later on she experienced an irritation about the vulva and could herself feel an object in the vagina. Although sceptical about her statement that "a snail had crept up her inside" I decided to investigate, and eventually removed a garden snail from the posterior fornix with a swab-holding forceps.

Corrigendum

The number of Mantoux-negative nurses referred to in line 12 of Dr. Snell's letter (Dec 9, p 768) should read 452, not 42. While the printer's error is large, Dr Snell's argument is unaffected.

if toxæmia is established or even in a mild case which persists more than three days. The fourth article to be rewritten is a valuable one on dermatophytosis, which replaces the one on seborrhoeic conditions. Like its predecessor, it is from the pen of Dr. H. W. Barber. Particularly important is the recognition of this condition between the toes, often caught by walking with bare feet on the floor of swimming-baths and changing-rooms. It may be responsible for two complications, the source of which may be overlooked. These are recurrent lymphangitis, which if unchecked may go on to a form of elephantiasis, and an allergic reaction, which may express itself in a vesicular eruption on the lateral aspects of the fingers.

RADIOLOGICAL LITERATURE OF 1943

The 1943 Year Book of Radiology. Diagnosis: edited by Charles A. Waters, M.D.; associate editor, Whitmer B. Firor, M.D. Therapeutics: edited by Ira I. Kaplan, M.D. (Pp. 456; illustrated. \$5.00.) Chicago: The Year Book Publishers, Inc.

Once again a review copy of the *Year Book of Radiology* comes to hand, with its wealth of information about the radiological literature of 1943. Because of the restrictions imposed by the war, the references are almost exclusively from American, South American, and British journals. As before, the book is in two sections; the diagnostic, occupying 272 pages, and the therapeutic 175.

In the chapter on the osseous system there are accounts of a number of papers of interest, including cases of osteopetrosis diagnosed *in utero*, chondro-osseous dystrophy with punctate epiphyseal dysplasia, Maffucci's syndrome, and Cooley's anaemia. Note is taken of Hartley's work on fatigue fractures, and cases are reported of Jungling's multiple cystic tuberculosis, and coccidioid infection of bone. In the respiratory tract two items of technique are described. Shapiro and Bell stress the importance of vertical radiography in infants, to differentiate pathological widening of the mediastinal shadow from postural. An apparatus for this is described. The other is an account of Farina's work on "mucosography" of the larynx, trachea, and bronchi, his method being to introduce a vaporized spray of neiodipin into the laryngeal vestibule. Further items of topical interest in this section are accounts of atypical pneumonia and blast injuries of the lungs. In the heart section there are two articles of interest on cardioangiography and four on venography. In the gastro-intestinal section there are accounts of many unusual cases, and a valuable study of the small intestine in infants and children by Zwerling and Nelson. The important work of Pendergrass and his collaborators, on hypersensitivity to contrast media for intravenous pyelography, receives due mention.

Again in this edition we find a comprehensive survey of the year's publications on radiotherapy. As in past years the annual is indispensable to those who wish to keep themselves *au fait* with current radiological work. Would that copies were obtainable in this country; but H. K. Lewis and Co. have been notified that it is already out of print.

Notes on Books

We have received the fifth edition of *Recent Advances in Anaesthesia and Analgesia*, by Dr. C. LANGTON HEWER (J. and A. Churchill: 18s.). That this book satisfies a need is shown by the fact that it is only a year since the last edition was published. It is all the more remarkable that in spite of this short interval of time so much new work has appeared. Included are such interesting developments as a laryngoscope based on a new conception of laryngoscopy, the production of general analgesia by the inhalation of ethyl chloride or by the intravenous injection of dilute procaine, the new improved absorber for controlled respiration, pethidine, and continuous caudal analgesia. Trichlorethylene seems to be given a disproportionately large amount of space. This is possibly due to the author's personal interest in this agent. As heretofore, the book is well produced and illustrated, and should without question be read and consulted by every anaesthetist.

The Substance of Mental Health, by Dr. GEORGE H. PRESTON (Jarrolds, Ltd.: 3s. 6d.), is an excellent little book designed for the layman, especially those concerned with the upbringing of children. Its great merit is that it is almost exclusively concerned with health and not with illness; in fact, mental disease is scarcely mentioned except, curiously enough, in the chapter entitled "What is Mental

Health?" The author is well versed in modern psychological theory, but refreshingly avoids the reduction of everything to terms of sex. Yet sex and sex difficulties are given their proper importance, and the chapter on sex education is eminently sane. He holds that the essential qualities making for mental health are: affection in the sense of trust, faith, and respect; praise, which of course should be deserved, though he rightly remarks that undeserved withholding of praise and encouragement does more harm than giving praise where it is undeserved; and consistency in the sense of freedom from rapid frequent unpredictable change. His final paragraph is worth quoting: These are the simple rules which seem to offer the basis for a setting in which mental health can grow. (1) Give, do not barter, affection, so that the child may feel "we" more often than "me." (2) Avoid the use of belittling, shame, or ridicule, so that the child may believe that he is worth while and capable of becoming a useful and desired adult. Do not be afraid to use praise. (3) Teach values and meanings which relate to the actual world in which the child lives. Be consistent; stick to a method which is yours, and do not try to be an omniscient saint. (4) Encourage independence and responsibility rather than obedience. (5) Remember that if you train a child properly you should lose him. Then your job is done and done well.

A pamphlet headed *Problems of Scientific and Industrial Research* has been published for Nuffield College by the Oxford University Press at 2s. This statement, which runs to about 60 pages, is the outcome of two private conferences held under the auspices of Nuffield College in January and April, 1944, and embodies the broad conclusions reached. It bears 92 signatures, including those of Sir Henry Dale, Dr. Charles S. Myers, Sir John Orr, and Profs. J. H. Burn, Arthur W. M. Ellis, J. H. Gaddum, R. A. Peters, and John A. Ryle. The signatories do not hold themselves committed to every particular, but they support strongly the general tenor of the recommendations in this statement and associate themselves with its underlying attitude as a contribution to current discussions of post-war economic and educational policy.

The seventh edition of *A Synopsis of Hygiene*, familiarly known as "Jameson and Parkinson," appeared in 1942 with Col. G. S. PARKINSON as sole author. An eighth edition (J. and A. Churchill: 25s.) has become necessary by reason of the large amount of information gathered and sifted under the stimulus of wartime conditions. Dr. G. P. Crowden is named on the title-page as author of the section on personal hygiene, and Col. Parkinson in his preface acknowledges the very active part taken by Miss K. M. Shaw in preparing the new edition. The opening section, on public health administration and the collection of vital statistics, is preceded by a brief summary of the Government's proposals for a National Health Service. The section which has needed most revision is that on prevention and control of disease. This book has now been before the medical public for 24 years and it has by no means outstayed its welcome.

Many facts not generally known or understood concerning contemporary religious history are summarized in *Man Power in the Twentieth-century Church*, by Canon J. McLEOD CAMPBELL, general secretary of the Missionary Council of the Church Assembly, which is published from 2, Great Peter Street, Westminster, S.W.1, price 2s. 6d. The book officially continues the series of *Unified Statements of the Needs of the Church Overseas*, and includes a chapter on medical ministries.

Preparations and Appliances

HOLLOW NEEDLE FOR REPAIR OF PERINEUM

Dr. J. S. LAURIE (Kinsley, nr. Pontefract, Yorks) writes:

Recent correspondence has prompted me to give a brief description of a method I have used for some years in repairing the perineum in general practice. In spite of what is said by the few, the fact remains that the vast majority of small perineal tears are repaired very efficiently and satisfactorily without an anaesthetic and half the equipment of a hospital.

I had made for me by Messrs. Thackray of Leeds a full curved hollow needle with a flat finger-grip at one end. This is sharp and of no greater dimensions than an ordinary intravenous needle. When the needle has been passed through both edges of the tear it is threaded from the base and the end seized as it emerges from the point; the needle is then withdrawn and the stitch tied off. There is no tugging of the double gut through the needle puncture, and patients who have suffered the old method are loud in its praise for painlessness.

The use of hollow needles for suture is not new, but its application in this respect does not seem to have occurred to many, and I commend it.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 9 1944

RATIONAL PHARMACOLOGY

The study of chemotherapeutic agents has passed through three stages. The first was purely empirical, with the discovery of the antimalarial action of quinine as its main achievement. The next stage may be called semi-empirical: the German method initiated by Ehrlich was to take a compound, which owing to its staining properties or for some other reason might be supposed to have a lethal affinity for the microbic cell, and to vary its structure through hundreds of permutations until the desired therapeutic effect was obtained. Hence the use of numbers—which have had many successors since 606—by which the position of a successful drug in a laboratory series is translated into a name. It was thus that prontosil was discovered, and the same method, involving the synthesis and rejection of thousands of other compounds, has produced the other sulphonamides in use to-day. During this time, and in connexion with many other antimicrobial agents than the sulphonamides, as well as with substances having altogether different biological effects, a constant aim has been to define relationships between chemical structure and biological activity. In so far as this is possible it defines and limits the field of further exploration by this method, and at best may point to the mechanism by which the desired effect is obtained. Ideally it would be far preferable to work in the reverse direction, arguing that a particular metabolic process essential to the life of the microbic cell should be arrested by a compound with a certain chemical structure; it should then be necessary only to synthesize that one compound to verify its effect experimentally. This has in fact now been done in several instances, and is the type of achievement to be expected in the third of the stages referred to, upon which we now appear to be well embarked.

The essential difference between the methods of 1908–40 and those which are possible to-day is that in the earlier period the mode of action of the drug was unknown, whereas we now recognize that chemotherapeutic agents arrest specific metabolic processes in the microbic cell. This concept of throwing a spanner in the works of intracellular metabolism—or, conversely, of oiling the machinery and so improving its work—has much wider applications than those involved in bacterial metabolism and hence in chemotherapy, but so far as this one aspect of it is concerned the door was opened by the studies of Fildes and Woods on the antimicrobial action of mercury perchloride and sulphanilamide respectively. Fildes proved that mercury salts arrest bacterial activity by combining with –SH compounds, which are essential metabolites for all bacteria, and that their effects can be neutralized by furnishing

such a compound in excess. Woods at the same time found that the effect of sulphanilamide on streptococci was due to competitive inhibition of an enzyme reaction in which *p*-aminobenzoic acid is utilized; this previously unrecognized factor is essential for the growth of certain bacteria, and these, of course, are the bacteria upon which sulphanilamide exerts its action. The effect of these discoveries on the theory of chemotherapy has been far-reaching; it is now accepted that all drugs having an antimicrobial action *in vivo* must act by some such mechanism, although in many cases it has yet to be identified. The best example of the deductive method it offers for arriving at new therapeutic agents is to be found in the work of McIlwain and Hawking,¹ in which pantooytaurine was postulated on entirely theoretical grounds as an antagonist to pantothenic acid, which is an essential growth factor for many pathogenic bacteria, and found both *in vitro* and *in vivo* to have the expected action.

These are some of the matters involved in a discussion on modes of drug action which occupied the Faraday Society at a remarkable meeting, of which it is fortunate that a full report has been published.² A recent number of the *British Medical Bulletin*,³ the purpose of which is to carry news of British achievements in medicine to many distant parts of the world, also contains admirable summaries of the main papers at this discussion. The new attitude to antimicrobial agents is reflected in the approach to antimalarial and trypanocidal drugs, and inquiry into the intimate mechanism of biological effect is carried into the sphere of narcotics and cerebral stimulants, and even insecticides and carcinogens. The outstanding new conception in this symposium, which is also the main subject of a more recent paper by McIlwain,⁴ is the dependence of biological effect on interference with vital enzyme systems. McIlwain defines five modes of such action, in connexion with all of which various substances either maintain normal function or disturb it; these substances vary from sulphonamides and alkaloids to vitamins and hormones. Anyone who reads this series of papers may justifiably take some pride in the fact that their contributors could be found in a single country which has been nearly five years at war.

EARLY DAYS AT JOHNS HOPKINS

The well-known Sargent portrait "Four Doctors"—Osler, Welch, Halsted, and Howard Kelly—serves as a reminder of the great good fortune of Johns Hopkins Hospital in obtaining such remarkable men for its original staff. Indeed the very brilliance of the quartette has tended to cast into the shade the careful and prolonged planning on which that institution was founded at Baltimore. This is corrected by the *Chronicle of the Johns Hopkins Hospital and University School of Medicine*,⁵ of which the first volume has now appeared. The founder's unusual Christian name was the surname of his great-grandmother. Johns Hopkins was a Quaker, and, the Society of Friends having strong objection to the marriage of first cousins,

¹ *Lancet*, 1943, 1, 449.² *Trans. Faraday Soc.*, 1943, 39, 319.³ 1944, 2, Nos. 3–4.⁴ *Nature*, 1944, 153, 300.⁵ Oxford University Press. (15s. 6d.)

he was unable to marry his only love, and so remained a bachelor all his days. He amassed wealth and, having no one to whom to leave it, decided to devote his money to the foundation of a university and hospital. In August, 1857, charters were granted and twelve trustees appointed, chiefly personal friends and Quakers. Throughout he was insistent that the two institutions were to be closely linked, a policy to which the trustees have strictly adhered.

Beyond clearing the site for the buildings little could be done until the death of the founder in 1873, when funds became available. There was much discussion about the type of building, and Dr. J. S. Billings strongly advised the "pavilion" pattern, then a novel idea. He became chief adviser to the trustees, and, in addition to his work in the Surgeon-General's office, where he initiated the *Index Medicus*, he helped greatly at every step of the project. Daniel Gilman proved to be a happy choice for the first President of the University, which was opened in 1876 by T. H. Huxley, who in his inaugural address insisted on the importance of a grounding in the preliminary sciences before the student entered on specifically medical studies. This is an attitude which has been faithfully maintained, together with the study of modern languages and philosophy—admirable adjuncts. The standard set was avowedly high. From the first Billings had in view the training of researchers and a school for nurses. Unfortunately, due for the most part to financial setbacks, twelve years were to elapse before the hospital could be opened, but the school for preliminary studies started before that. Remsen was appointed professor of chemistry, while Newell Martin, who had been Michael Foster's assistant at Cambridge, took charge of the biological sciences, and quickly attracted a number of research workers who were destined to leave their mark on American medicine. But his health failed early in life and he had to retire in 1893, just as the scheme was approaching completion. In 1884 W. H. Welch was appointed professor of pathology, to the great benefit both of the school and of that science. It is interesting to read that unsuccessful attempts were made to attract first Lauder Brunton and then Matthew Hay to the chair of pharmacology. Owing to the delay in opening the hospital, members of the clinical staff were not appointed till

1888, when Osler became chief physician and professor of medicine. No happier choice was ever made, and the suggestion came from Welch. Five months later Halsted was made acting surgeon, but was soon promoted to substantive rank with a professorship. He was a fine scientific investigator rather than an attractive teacher. The quartet was completed by the appointment, at Osler's recommendation, of Howard Kelly as gynaecologist. In 1889 postgraduate classes were started despite some opposition.

The curiously piecemeal stages in the evolution of Johns Hopkins were due to the fluctuating income from the trust fund, and even by 1890 there seemed little prospect of a complete undergraduate medical school. Then a group of Baltimore ladies came forward with an offer of \$100,000, on the condition that women should be admitted on equal terms. The most generous donor was Miss Mary Garrett, who altogether gave rather over \$350,000. But she laid down her terms in no uncertain manner, being insistent

that a high standard should be exacted from entrants; much so that Osler said: "Welch, it is lucky that we are in as professors; we could never enter as students." However, finally all was settled harmoniously, and the school was completed by the addition of J. J. Abel in charge of pharmacology, F. P. Mall anatomy, and W. H. Howell physiology. All was set fair for the complete university medical school, and hospital by 1893, which brings to a first volume of this history to a conclusion.

It is indeed a remarkable story, which needed telling, and Dr. Alan Chesney has told it attractively, even if his loyalty has perhaps sometimes made him rather too discreet. If Johns Hopkins has not retained its initial pre-eminence this is as much due to the rise of other institutions as to any decline in itself. Many distinguished men have added to its lustre—too many to mention individually. We are left with a vivid impression of the far-sighted munificence of the founder and Miss Garrett, of the skilful planning of J. S. Billings, and the diplomacy of Daniel Gilman. But the success of their plans was dependent on the two great creators of the prestige of the medical school—W. H. Welch and William Osler.

CONTROL OF OEDEMA IN BURNS

The exudation of fluid into burnt tissues is significant for two reasons: first, it is an important cause of shock; and secondly, its persistence delays healing and return of function. Much can be done by intravenous replacement to counteract the effects of fluid loss, but measures to prevent it have been disappointing. Experimental evidence of the value of such measures is welcome, even if their use in clinical work is difficult. Sellers and Willard¹ found it possible to prevent swelling by the application of plaster-of-Paris immediately after burning. Their experiments were done on dogs burnt on the legs by immersion in hot water. The legs were at once encased in plaster bandages without pressure. If the casts were removed at 24 hours the legs looked normal, but soon swelled like the controls. At 48 hours they swelled less, and at 72 hours hardly at all. The most striking effect of this treatment was the reduction of mortality, 20 of 38 controls dying, but only 2 of 36 treated dogs. That the reduction in mortality was due to inhibition of fluid loss was suggested by studies of haemoconcentration, which was fully controlled when the extent of the burn allowed complete covering with plaster and slight only in more extensive burns. In other experiments the authors studied the effects of cooling combined with external pressure by fitting double rubber sleeves to the burnt legs through which cold water was circulated at measured pressures; the purpose of the cooling was to reduce metabolism and local toxin formation. As in the "plastered" animals, mortality and haemoconcentration were reduced, but apparently not so effectively. Although plastering fully controlled the swelling, bloody diarrhoea and haematuria were observed in both treated and control animals, being, however, more severe in the latter. In both groups, too, haemolysis appeared in blood samples within an hour of burning. These findings were taken as evidence for the existence of other factors in burn shock than fluid loss, although the results of their experiments point to the predominant importance of this factor. The fact that no better results were obtained by combining cooling with pressure might suggest that toxin formation

¹ *Canad. med. Ass. J.*, 1943, 49, 461.

was not important, but it is not clear that the rubber sleeves controlled fluid loss as efficiently as plaster.

In all these experiments treatment was started immediately after burning, and it is known that the fluid loss is very rapid, about 50% occurring in the first 30 minutes. Herein lies the difficulty of the clinical application of such methods. Bearing on this point is the work of Rossiter, who has also devised experiments to show that oedema can be controlled by pressure. He has applied his methods in small animals both immediately after burning and at an interval of three hours, and although, as is to be expected, the immediate application is the more efficient, his animals treated at three hours showed much less oedema than controls. His experiments were not concerned with mortality, most of the animals being killed after short intervals. We cannot say to what extent the results obtained by Sellers and Willard were dependent on the time factor. Although external pressure is not easily applicable to human burns, it would seem to be more rational than plaster for cases in which treatment is delayed until oedema has formed. There are few parts of the body to which pressure is easily applied except the limbs, and it must be noted that in the experiments described the authors were able to adapt the burns to the apparatus devised for their treatment. The application of controlled pressure to human burns is likely to require much supervision and can have little place in the treatment of war burns. At present the fear of embarrassing the circulation rules out the use of plaster, at least until the patient is under continuous observation in hospital, and by that time it will be too late to prevent oedema. There seems no doubt, however, that the control of oedema is desirable, and that if a safe and practicable method could be devised it would mark a great advance in treatment.

COMMUNAL HEALTH

If a medical man expressed the opinion that the wisest of our authors have been those who had received a medical training, to cite Locke, Arbuthnot, Holmes, William James, and Bridges might not be a sufficient defence of an "old school tie" partiality. We recall, however, a remark of James Payn that he found the conversation of doctors broader minded than that of other professional men; Prof. E. P. Cathcart's pamphlet *Communal Health*¹ illustrates what Payn meant. Prof. Cathcart first describes *sine ira et studio* the sanitary conditions of great cities in England and Scotland a hundred years ago. He does not, as some historians do, leave it to be inferred that the unspeakable filth and squalor recorded in the quotations were universal, but carefully indicates that many working-class people lived tolerable, even happy, lives. He does, however, make it quite clear how great a mass of preventable evil existed, and that a toll was taken of human life, in comparison with which the sufferings of these evil times, though far from trivial, are small in point of numbers of deaths and death rates. Next he describes the change effected when, at long last, the views of social pioneers—the Chadwicks, Simons, and Shaftesburys—became public opinion. Finally he turns to the future. Prof. Cathcart writes at some length on two major uncertainties—the future of the birth rate and the use of leisure; on each what he has to say is wise. If, as he holds, refusal to produce children is due to malaise of the spirit, these two questions are interrelated. Why should any human being with Macbeth's view of life bring into the world others to listen to a tale told by an idiot? One's work is monotonous; the only joy in it is to have work at all, and that is haunted by a fear of unemployment; one's leisure

becomes monotonous too—the pictures, the dogs, football arenas, and not much else. Such was probably the view of a great many young married men between 1920 and 1939. Much can be done to remedy the fear of unemployment and improve the conditions of work no longer precarious so that they will command the unanimous approval of the population concerned. But to make leisure less monotonous, to free millions from dependence on professional entertainers, to enable them to amuse themselves, is a matter of education, and (as Prof. Cathcart points out) we cannot force people to learn, the best use of leisure: our people are not German sheep. "But we can see to it that every means is employed to discover the causes and to restrict the opportunities for misspent leisure." This pamphlet deserves wide circulation.

CAROTINAEMIA AND HYPERVITAMINOSIS A

Clinical carotinaemia, due to excessive consumption of foods rich in carotene, the precursor of vitamin A, is well known.¹ It is characterized by xanthosis of the skin, sometimes by yellow cutaneous nodules rich in carotene, and by a raised serum carotene. It occurs in patients suffering from diseases associated with hyperlipaemia, such as diabetes, nephrosis, and hypothyroidism. Generally speaking, this carotinaemia is symptomless, although loss of weight, asthenia, and hypotension have been reported.² Such symptoms may be due not to carotinaemia *per se* but to associated conditions or even to inadequate diet, since foods rich in carotene are mainly vegetables. On the other hand, information on hypervitaminosis A, a condition resulting from excessive intake of vitamin A, is scanty. Josephs³ has now published a report on a case of hypervitaminosis A in a boy of 3 who was given a teaspoonful of halibut-liver oil (containing about 240,000 i.u. of vitamin A) daily from the age of 2 months. The child developed an abnormal liking for the oil, so much so that on occasion he drank it from a bottle in almost unlimited amounts. The hypervitaminosis A that ensued was characterized by hepatomegaly, splenomegaly, hypoplastic anaemia, leucopenia, increased serum vitamin A and lipids, advanced skeletal development, clubbing of the fingers, and sparse coarse hair. Most of the symptoms cleared promptly on discontinuing the halibut-liver oil. It has long been known by explorers that bear's liver has toxic properties if eaten by human beings, the symptoms being vomiting, drowsiness, irritability, severe headache, and exfoliation of the skin. Tests on rats by Moore and Rodahl⁴ suggest that this may be due to its high vitamin A content.

Why should an abnormal intake of carotene be relatively harmless, yet the vitamin itself give rise to toxic symptoms? Increasing the dietary intake of vitamin A beyond a certain optimum increases the amount stored, but it is usually not possible to push the level of the vitamin in the blood above a normal maximal value except for a few hours. There is probably a mechanism for the maintenance of the level of vitamin A in the blood within certain limits. It may be significant that this mechanism exists in the case of vitamin A, which can have toxic effects, and not in the case of its precursor, carotene, which is relatively harmless. Another protective mechanism is the storage of vitamin A in the liver, where it seems to be harmless. It is not the total amount of vitamin A stored in the body that determines the onset of toxic symptoms but the presence of quantities large enough to overwhelm the

¹ Almond, S., and Logan, R. F. L., *British Medical Journal*, 1942, 2, 239.

capacity of the liver to remove it from the blood.⁵ It is apparently possible to raise the storage in the liver to high levels, and no symptoms of intoxication follow unless the daily consumption is raised above the "toxic" level. In the removal of vitamin A the cells of the reticulo-endothelial system play a primary part, particularly the Kupffer cells of the liver.^{6,7} There is no danger of clinical hypervitaminosis A if vitamin A, or concentrates containing it, are prescribed in therapeutic doses. Joseph's patient received 240,000 i.u. daily—a truly excessive dose—for about three years. The optimum daily requirements are from 1,500 i.u. daily for the infant to 8,000 i.u. for the nursing mother.

SOME CAUSES OF STERILITY

Interest in human sterility and infertility has been much intensified in recent years, and is by no means confined to the medical profession. Alarm is felt by many at the decline in the birth rate, and, although much infertility is undoubtedly voluntary, there are many marriages in which the desire for a child remains unfulfilled. The problem is complicated by the many factors, involving both partners, which may be responsible. Sharman⁸ has recently published a careful study of 500 cases of primary sterility, and, though he does not claim that this is in any way a comprehensive survey, he presents much new material and some contrary to orthodox teaching. In describing the results of tubal insufflation with gas, he stresses the value of the kymographic tracing, which, he has found, is relatively constant for the same patient even over several months and at different times in the menstrual cycle. An increase in tubal peristalsis is observed at about the time of ovulation. Anaesthesia has little effect on the tracing. An isolated tracing indicating apparent non-patency is not necessarily evidence of tubal occlusion. Hystero-salpingography with lipiodol only occasionally reveals the patency of tubes thought to be occluded on the evidence of gas insufflation. Interpretation of x-ray films obtained by lipiodol hystero-salpingography is often difficult; the main advantage of the method is that where tubal occlusion is found the film may indicate the site of blockage.

Histological examination of the endometrium in patients in the premenstrual phase revealed anovular menstruation in 6.4% of 358 patients so examined. A further and more striking finding was the presence of unsuspected tuberculosis of the endometrium: in the first series of 392 patients tuberculosis was found in 5.1%, and in a later series in 5.3% of 883 cases. Tuberculosis of the endometrium, without involvement of the tubes, is probably commoner than is generally realized. This is certainly the opinion of Sutherland,⁹ who published the results of the histological examination of over 5,000 samples of endometrium and of 864 uteri. He found tuberculosis of the endometrium in 1.1% of endometria removed by curettage and in 1.4% of the uteri examined. Twenty-four of the patients with this form of tuberculosis complained of sterility, and in 20 the tubes were occluded. Bacteriological confirmation was obtained by guinea-pig inoculation: 10 out of 16 inoculations were positive. All this suggests that sub-clinical tuberculosis of the female genital organs is a not uncommon cause of sterility. The finding of anovular menstruation and unsuspected tuberculosis in cases of sterility—the two accounting for over 11% of the patients in Sharman's series—makes it clear that endometrial biopsy is an essential part of the investigation of these patients. Congenital occlusion of the tubes is, in his opinion, un-

common—a view based on the examination of unmarried women and on tests for tubal patency carried out post mortem in female infants and young children. Sharman believes it is unusual for the gonococcus to reach the Fallopian tubes, and that occlusion from this cause is unlikely in the absence of palpable thickening of the tubes. But subclinical tuberculosis he considers a common cause of occlusion.

Out of 409 patients treated for sterility 28.3% became pregnant. Of the remaining 293 sterile marriages there was some factor which made pregnancy unlikely or impossible in 52%. In no case of tuberculosis or of azoospermia did pregnancy result, and in the cases of anovular menstruation only two women who had received treatment became pregnant. In 141 cases, or 48% of the 293 sterile marriages, no cause for infertility could be found. Sharman comments that opportunities for coitus, restricted by separation of the partners owing to the war, may arise at an infertile period in the menstrual cycle and so in some cases result in a physiological infertility.

Sharman's paper is an important contribution to the problem of sterility. The high incidence of uterine tuberculosis is probably the most striking finding, and it will be interesting to know if this is a purely local phenomenon, limited to the Glasgow area, from which presumably most of the patients in this series were drawn.

HEPATIC INJURY

Lipotropic substances prevent or control the deposition of fat in the liver. This group of biologically active agents has been extensively studied since Hershey's¹ description in 1930 of the prevention of fatty livers in depancreatized dogs by feeding with lecithin. Hershey, Best, and Huntsman² later showed that lecithin could be replaced by choline. In 1935 Channon and Wilkinson³ described the lipotropic action of casein, and the anti-lipotropic effect of cystine. Two years later Tucker and Eckstein⁴ demonstrated that the effect of casein was due to its contained methionine. More recently du Vigneau⁵ and his associates have demonstrated the importance of methionine in the biosynthesis of choline by transmethylolation. It seems probable that this group of lipotropes are linked together and that all are intimately concerned with the supply of choline for phospholipin synthesis. Other lipotropic substances have been described, such as lipocaine by Dragstedt⁶ and inositol by Gavin and McHenry.⁷ The lipotropic action of these substances can be distinguished in various ways from the choline group, but their mode of action is at present unknown. McHenry⁸ has shown that thiamin and other members of the vitamin-B complex have a marked effect on fat deposition in the liver. Extensive fatty deposition in the liver did not occur in rats fed a choline-free diet if the thiamin in the diet was also deficient.

This extensive investigation of lipotropic substances has obvious importance in the study of fat metabolism, but György and Goldblatt⁹ have shown that it may have an even wider significance. These workers found that hepatic injury superimposed upon fatty infiltration could be irregularly produced by dietary means. György,¹⁰ in a recent publication, has described further experiments on rats, in which he was able regularly to produce hepatic injury

with a diet deficient in lipotropic factors. The hepatic injury was prevented by the introduction of lipotropes into the diet, and investigations are proceeding into the therapeutic use of lipotropes once hepatic injury has been established. Preliminary studies of this aspect of the work are encouraging. The changes in the rat livers consist of fatty infiltration (and sometimes fatty degeneration), a diffuse or focal necrosis, and varying degrees of cirrhosis. These changes resemble those seen in many types of liver poisoning, such as that due to carbon tetrachloride, but in dietary hepatic injury the distribution is not so uniform, haemorrhage is greater, and fatty degeneration usually less marked. The necrosis is as a rule central or mid-zonal, but the cirrhosis is periportal, and the final picture is similar to that seen in Laennec's cirrhosis in man. The only real distinguishing point is the presence of pigment globules of light yellow or greenish-yellow colour in the "dietary" cirrhotic livers. The nature of this material has not been determined, but it is probably a lipo-protein substance and has been termed 'ceroid' by Lillie.¹¹

Gvory draws attention to the similarity of the changes in these experimental animals to pathological changes in man. While there is obvious danger in drawing a direct analogy between dietary cirrhosis in the rat and hepatic injury in the human subject, the mass of evidence on the physiological side demands investigation in the clinical field. The case is strengthened by the fact that many rats with hepatic injury produced by dietary means also have renal damage. This combination may be analogous to the hepato-renal syndrome in man or such conditions as eclampsia, in which hepatic and renal injury frequently occur together. Gvory suggests for human cases certain preventive and therapeutic measures based upon his experimental work. He advises a diet containing a high level of protein and restricted fat. The protein should have a high methionine content, and the fat should be rich in unsaturated fatty acids and low in cholesterol. The diet should contain all the members of the vitamin B complex carefully balanced. In addition to the dietary supply it is suggested that methionine should be administered in doses of 2 to 4 grammes daily, or, alternatively, cystine plus choline in similar doses could be used, but this is probably not so effective.

It seems likely that at least some cases of hepatic injury and subsequent cirrhosis do not present irreversible changes due to direct toxic action, which has been the general view for many years, but that these lesions may be both preventable and reversible. This new conception affords an opportunity for full co-operation between physiologists and clinicians in carefully controlled clinical trials.

MEASURES AGAINST PNEUMOKONIOSIS

The Ministry of Fuel and Power has now issued through H.M. Stationery Office¹ the report of the Advisory Committee on the Treatment and Rehabilitation of Miners in the Wales Region suffering from Pneumoconiosis, the term applied to pulmonary abnormalities found in colliery workers underground and on screens, and in coal trimmers at docks described as due to the inhalation of dust. Already measures are being taken to prevent the contraction of the disease by the suppression of harmful dusts at working places in mines but further attention needs to be given to the treatment of affected persons and to their restoration to a state of health and fitness for appropriate employment. The committee was set up primarily to consider this aspect of the problem. It finds that present knowledge of the disease is insufficient to enable it to advise

the introduction of large-scale measures of treatment, including rehabilitation, and that further research is necessary. Accordingly it recommends the establishment of a research unit with accommodation for about thirty patients, equipped with facilities for clinical study and investigation, the work of this research unit to be linked, through a central authority, with that proceeding on other phases of the problem—e.g., to acquire more precise knowledge of the causes and of the diagnosis of the disease, to develop and apply in the pits better methods of suppressing the dangerous dust, and to retrain and resettle partly disabled miners who are fit to take up other more suitable employment. It also recommends the initial and periodical clinical and x-ray examination of miners and the correlation of the findings of such examinations with the results of pathological research into early changes in lung condition, the progression of those changes, and the part played by tuberculosis and other infections. The establishment of a co-ordinating Pneumokoniosis Bureau is advised. The medical members of the committee were Drs E. A. Aslett, T. H. Jenkins, N. Keating, Prof. C. Bruce Perry, and Dr. T. W. Wade.

SANDFLY FEVER

Fourteen American soldiers who volunteered to submit to experiments which increased the knowledge of sandfly fever, encountered by American fighting men in tropical and semi-tropical regions, have been awarded the Legion of Merit, the U.S. War Department announced on August 3. The soldiers were infected with the disease, the fever being produced in some by small injections of blood from individuals who already had it, and in others by exposure to repeated bites of infected sandflies. Sandfly fever, or "phlebotomus fever," is caused by bites of sandflies carrying the infective agent, a filterable virus. The fly is about an eighth of an inch long, and only the female bites. The puncture of the skin is usually painful. The fever is not contagious, but is transmitted by the bite of a sandfly that has bitten an infected person. The onset of the sickness begins two or three days afterwards and results in symptoms not unlike influenza. The patient is incapacitated for one or two weeks, although his temperature, going as high as 102° or 104° F., usually subsides in about three days. Experiments showed that the virus causing the fever in the Middle East was the same as that infecting soldiers in Sicily. The active virus obtained from Sicily was injected into healthy individuals. They fell ill with sandfly fever. After recovery they were injected with the virus from Egypt but did not contract fever, proving that Sicilian sandfly fever attacks confer immunity against the Egyptian virus. The studies, started in April, 1943, in the Middle Eastern theatre, were directed by Dr. John R. Paul, Consultant to the Secretary of War and Director of the Surgeon-General's Commission on Neurotropic Virus Diseases, who flew into the area with Major A. B. Sabin, Army virus expert, and Major C. B. Philip, entomologist.

In a field laboratory six kinds of monkeys and other animals were tested before the experiments on the soldiers. None of the animals was found susceptible to the disease. The soldiers volunteered for a second series of experiments, resulting in finding two chemical insect repellents, dimethyl phthalate and pyrethrum-containing vanishing cream, which successfully prevent sandfly bites. The material was applied to exposed body areas and found effective for eight hours. In making the test infected sandflies were released in the volunteers' sleeping quarters. Only those who had not applied the repellents were victims of the fever.

TECHNIQUE OF BLOOD EXAMINATION FOR MALARIA PARASITES

BY

T. CRAWFORD, M.D., B.Sc., F.R.F.P.S.

Major, R.A.M.C.

Many practitioners, medical officers, ship surgeons, and laboratory workers formerly not familiar with malaria are now being confronted with its diagnostic problems. The technique involved in the blood examinations is simple enough, but it is not widely realized that a staining technique giving the best results for blood cells does not do so for malaria parasites. Faulty methods often lead to a failure to detect parasites present in small numbers, so the following brief notes may guide workers inexperienced in this field.

Materials and Reagents

A sharp cutting skin needle, gauze or wool swabs, and some spirit or ether are required for the skin puncture.

Slides.—Thin half-white slides, clean and free from grease, are best for this work; scratched or frosted slides should be avoided. In an emergency, slides as supplied by the makers, if held by the edges, breathed on, and polished with a clean cloth, will usually give satisfactory results. Whenever possible, however, the slides should be cleaned chemically by boiling for five minutes in a solution containing 6% each of potassium bichromate and sulphuric acid, and then washing in running tap-water for 10 minutes; the slides are then stored in spirit and polished before use. Chemical cleaning is essential in certain tropical regions to prevent the growth of moulds.

Leishman's Stain.—Sold as a powder or in tablets of known weight, the staining solution is prepared as follows:

Place 0.15 g. of the stain in a small mortar and measure out 100 c.c.m. of pure methyl alcohol (acetone-free). Grind the dry powder and then add about 20 c.c.m. of the methyl alcohol. Grind again for a few minutes and decant into a clean dry bottle with a well-fitting ground-glass stopper. Repeat with successive small quantities of the alcohol; the last two portions should be only faintly tinged with the stain. If pestle and mortar are not available satisfactory results may be obtained by placing the stain in the bottle, adding the methyl alcohol, and shaking vigorously for five minutes on three occasions.

Freshly prepared solution does not give the best results, so the stain should be kept in a dark cupboard for 10 days, shaking vigorously every day, and then placed on a shelf in ordinary daylight (avoiding direct sunlight) for seven days before being used. The stain should not be filtered, and no attempt be made to hasten its solution by heat. The bottle should be kept carefully stoppered, as contact with the air speeds deterioration. When required for use the stain should be removed from the bottle with a pipette; the last half-inch of solution is best discarded, as it always contains some granular deposit which may cause troublesome artefacts in a stained blood-film. If correctly made and stored, Leishman's stain keeps indefinitely in a temperate zone, but deterioration may be rapid when temperature and humidity are high.

Giemsa's Stain.—This is supplied in solution, and has only to be diluted for use. It is thus more suitable than Leishman's stain for occasional use away from a laboratory. The undiluted stain keeps well and is not affected by heat and humidity.

Distilled Water.—This is a most important reagent, and consistently good results cannot be obtained unless it has the correct pH concentration. The best staining of blood cells is obtained when the water used for dilution and washing has a pH value of 6.8 to 7.0. For malaria parasites, however, the best results are obtained at a pH of 7.2. At this pH value the red blood corpuscles give a slightly bluish staining, against which the bright red and deep blue of the parasites stand out boldly. In addition the weakly basic reaction accentuates the earliest changes in the parasite-containing corpuscles, which are an important feature in species diagnosis. As taken from the still, distilled water is almost always slightly acid owing to the absorption of carbon dioxide from the air in cooling. One of the following methods ensures that a diluent of the desired reaction (pH 7.2) is employed.

(1) 9 g. of anhydrous disodium hydrogen phosphate and 1.8 g. of anhydrous potassium dihydrogen phosphate are dissolved in 3 litres of distilled water. This buffer salt solution is recommended for use wherever frequent examinations are carried out.

(2) About 4 c.c.m. of bromothymol blue indicator solution is added to a litre of distilled water. This gives a yellow colour owing to the acid reaction. A 0.5% solution of sodium carbonate is now added drop by drop, with vigorous shaking, until the water attains and retains a bluish-green colour. This indicates a

pH of about 7.2, but is less accurate than the use of buffer salts described above.

(3) In emergency, if distilled water or filtered rain-water is boiled vigorously for 5 to 10 minutes it usually attains a pH of 7 to 7.2 and allows fairly satisfactory staining. The acid reaction returns on standing.

Spreading the Blood Films

(a) **Thin Films.**—The slides are placed flat on a bench or bedside table and one with a perfectly smooth edge is chosen as a "spreader." Shorten the spreading edge by about 1/4 in. by chipping off one corner: both edges of the resulting smears can be readily examined. The patient's finger and the needle are cleaned and dried and a slight incision is made above the base of the nail. A small drop of blood is allowed to collect, and this is lifted with the under surface of the edge of the spreader, held by the edges in the right hand. The blood is now touched down on the slide to be spread, about an inch from the right end, and allowed to run across the width of the spreader. The free end of the spreader is lowered to make an angle of 20 to 25° with the horizontal, and is then pushed smoothly and firmly to the left end of the slide. A really thin film, with the red cells lying separated, is essential for the accurate diagnosis of malaria parasites. The two factors which control the thickness are the amount of blood and the angle at which the spreader is held—the less the amount of blood and the lower the angle, the thinner the resulting smear. The films are allowed to dry at room temperature, and should not be heated.

(b) **Thick Films.**—The advantages of the thick film technique may be entirely lost if attention is not paid to technical details. In particular, the beginner should eschew certain ultra-rapid methods that have recently become fashionable. The term "thick" is purely relative, and a common mistake is to make the smears too thick. A drop of blood similar to that used for a thin smear should be lifted on the centre of a slide and spread out with the blade of the needle until a page of print can be clearly seen through it. The film is allowed to dry horizontally, protected from dust and insects. Drying may be hastened by placing the slide for a few minutes in an incubator at 37° C.; but more vigorous heating interferes with subsequent dehaemoglobinization.

Staining

(a) **Leishman's Stain for Thin Films.**—The slide is supported in a horizontal position and 10 to 12 drops of the stain are placed on the film, using a clean dry pipette. The stain is spread out with the barrel of the pipette to cover the entire area of the film, and is allowed to act undiluted for about 30 seconds, thus fixing the blood. Double the quantity (20 to 24 drops) of pH-adjusted distilled water is then added, and is mixed with the stain by drawing up and expelling two or three times with the water pipette. The precise time the diluted stain should be allowed to act varies with different batches of stain. The period is usually between 10 and 20 minutes, and the best results are obtained by somewhat longer staining than for blood cells. At the end of the staining period the stain should not be poured from the slide but gently flushed off in a stream of distilled or tap water for a few seconds only. This prevents the scum which forms on the surface of the stain from settling on the film and showing as a granular deposit, but more prolonged washing will rapidly decolorize the parasites. The film should be allowed to dry in a semi-vertical position without heat or blotting.

(b) **Leishman's Stain for Thick Films.**—Haemoglobin is removed from the preparation by placing the dry unfixed film in an upright position in a jar of distilled water. When the film is uniformly white—in about 10 minutes with a fresh film—it is gently withdrawn and allowed to dry. The dehaemoglobinized film is then stained as the thin films, except for a rather shorter staining time (5 to 15 minutes).

(c) **Giemsa's Stain for Thin Films.**—As this is a watery solution the films must be treated with a fixing reagent before staining. The surface of the slide is flooded with absolute methyl alcohol, which is allowed to act for one or two minutes. The slide is then washed gently in a stream of tap-water and placed vertically or face downward in a staining jar or dish containing Giemsa's stain diluted in the proportion of two drops of the stain to each c.c.m. of pH-adjusted distilled water. The staining is complete in 20 to 30 minutes; the slide is then quickly rinsed and allowed to dry in a semi-vertical position.

(d) **Giemsa's Stain for Thick Films.**—Without previous fixation the films are placed vertically or face downward in a staining jar or dish containing the diluted stain—one drop of stain to each c.c.m. of distilled water. The vessel is gently agitated from time to time, and dehaemoglobinization and staining are complete in 20 to 30 minutes. The slides are then gently transferred to a dish of water for a few seconds only and finally allowed to dry in a semi-vertical position. Vigorous handling or washing in running water may cause the film to leave the slide. Dilutions of Giemsa's stain remain active for about 12 hours, during which time they may be used repeatedly.

KENNY TREATMENT OF POLIOMYELITIS

REPORT BY AMERICAN COMMITTEE

A committee to study and evaluate the Kenny treatment of infantile paralysis was set up in June, 1942 comprising members of the American Orthopedic Association, the American Academy of Orthopedic Surgeons, and the Section on Orthopaedic Surgery of the American Medical Association. The report of the committee was presented at the annual meeting of the American Orthopedic Association and at the annual meeting of the American Medical Association held in June, 1944. This has now been published under the names of Drs. Ralph K. Ghormley, Edward L. Compere, James A. Dickson, Robert V. Funsten, J. Albert Key, H. R. McCarroll, and Herman C. Schumm.¹

The committee in the course of its study visited six cities and sixteen clinics, some of them two or more times. A total of approximately 740 patients were examined, of whom about 650 had been treated by the method advocated by Miss Elizabeth Kenny. Some of these patients represented examples of cases from earlier epidemics, while the majority came from epidemics occurring since 1940. Early in the investigation questionnaires were sent to over 900 orthopaedic surgeons, but no definite conclusions could be drawn from the reports they submitted. The committee notes that one of the things Miss Kenny has stressed is the difference of her treatment from what she calls "orthodox" treatment, but it finds difficulty in understanding what she means by this epithet. In the United States several different plans of treatment have been followed in the work with poliomyelitis. As long ago as 1917 R. W. Lovett outlined a method of treatment which was pursued successfully for many years, and is still the basis of most modern therapy in that country. For many years the use of pools has had a prominent place in the treatment of anterior poliomyelitis.

The report discusses Miss Kenny's concept of the disease, in which the four major points stressed by her are muscle 'spasm', mental alienation (functional dissociation), incoordination of muscle action, and paralysis (or 'denervation'), and criticizes each in turn. It next describes the Kenny treatment under ten categories and follows this with the analysis and discussion reproduced below.

The Treatment Analysed

1 The institution of treatment directed toward the involved muscles as early as possible is desirable, but the general condition of the patient during the acute febrile stage may be such that the handling necessitated by the Kenny treatment can be detrimental.

2 Proper positioning in bed by one means or another has been a standard practice among physicians for over thirty years to our knowledge. It is still a recommended procedure.

3 Heat in some form, including hot fomentations, has been used by physicians for many years to combat pain in infantile paralysis. In most instances the pain can be relieved by the use of hot fomentations. We have seen a few cases, however, in which relief was not afforded by their use. It is the impression of this committee that pain is not an important feature of the disease in most instances, and, when present, can be relieved also by other measures. Recovery from 'spasm' in most instances takes place spontaneously. Hot packs may relieve this "spasm," but so will adequate rest. Therapy directed at pain and "spasm" should be discontinued as soon as these symptoms subside. We have seen instances in which hot packs seem to increase and prolong the "spasm." In some, "spasm" was relieved after the packs were discontinued. In others, "spasm" which had been relieved recurred when the packs were discontinued and was again relieved by their reapplication. The use of hot fomentations therefore cannot be considered as a panacea in this disease, and their use must be guided by good medical judgement. The rigid technique insisted on by Miss Kenny in the application of these packs is neither important nor essential.

4 So long as active and passive movement of these extremities is carried out within the range of comfort, this point is acceptable. This procedure has been recommended by many physicians in the past, but again we stress the point that this movement should not be forced beyond the point of pain.

5 Jones and Lovett described and used a method of muscle re-education which in principle is similar to the method taught by Miss Kenny. This has served as the basis for orthopaedic treatment for many years.

6 Cases have been seen under Kenny treatment in which early contractures were developing, and by application of plaster splints these contractures were controlled after their correction. This committee believes that splints are beneficial for some patients. Braces should form an important part of the treatment during the later stages of this disease. We have seen Kenny treated patients walking with two English style crutches who could be so benefited by braces that the crutches could be discarded, thus liberating the hands for other use.

7 Respirators have saved many lives and should be used for patients with sufficient paralysis to embarrass respirations.

8 There is no evidence that the Kenny treatment prevents or decreases the amount of paralysis. We criticize severely the oft-repeated statement of Miss Kenny to patients who have come to her after treatment elsewhere that had this case come to her early the disability would have been prevented. Such statements are not founded on facts.

9 Spontaneous recovery in poliomyelitis occurs in many cases. Reports in the medical literature indicate that this varies in different epidemics from 50 to 80%. We have seen many patients receiving Kenny treatment who showed no muscle involvement at any time, yet she assumes the credit for their satisfactory results and does not take into account the factor of spontaneous recovery.

10 Pools and baths have long been used in the treatment of poliomyelitis.

The Committee's Commentary

In its general comment the report condemns Miss Kenny's objection to muscle examinations, and hence the lack of accurate records. With regard to her repeated statement that under "orthodox" treatment only 13% of patients recovered without paralysis while under her treatment over 80% recover, the committee believes this to be a misrepresentation of the facts of treatment by other methods, which it attributes to her over zealous desire to promote further the adoption of the Kenny treatment. In refutation of the belief of some people that paralysis can be prevented when treatment is started before the onset of paralysis it says, 'We have seen enough cases in which the Kenny treatment was instituted very early to be convinced that this does not prevent or even minimize the degree of permanent paralysis. Further, in several cases seen by its members the paralysis progressed after the Kenny treatment was instituted.' It emphasizes that the prevention of early contractures is the primary means by which medical care is able to minimize the effects of the disease. In its opinion, after observation of 740 cases, the continuous employment of hot packs for all patients with minimal evidence of 'spasm' is of questionable value, and a waste of man-power and hospital beds. Good medical judgment is required in determining the cases in which hospital treatment should be instituted or continued.

With regard to Miss Kenny's claim to a new and revolutionary discovery by means of which she can diagnose the disease and determine the involved extremities before the onset of the usually recognized diagnostic clinical signs, and her claim that the institution of her treatment at this time will control pain and prevent paralysis, the committee says that the preparalytic diagnosis of poliomyelitis was described by Draper (1931) and by Aycock and Luther (1928), and that no satisfactory evidence has been presented to it that the institution of early local treatment will alter the course or the extent of the paralysis in any case. Commenting on the claim that all paralytic scoliosis can be prevented by Miss Kenny's programme of care the committee says that several more years must elapse before any final conclusion can be reached with regard to the amelioration or prevention of paralytic scoliosis by means of the Kenny treatment. Lastly, while it condemns the wide publicity which has misled the public and many members of the medical profession, it acknowledges that this has stimulated the medical profession to re-evaluate known methods of treatment of infantile paralysis and to treat it more effectively.

J. Chasnoff and J. J. Vorzmer (*Ann. intern. Med.* 1944, 20, 327) state that temporal arteritis is a disease of unknown aetiology which is seen in elderly patients and is more frequent in females. The outstanding subjective symptoms are headache, malaise, and weakness. In most cases there is a low grade fever. Marked secondary fever is constant and slight leucocytosis common. The disease runs a protracted course of 4 to 12 months, but relapses are frequent. Complete recovery occurs in most cases.

MASS RADIOGRAPHY

A Cautionary Notice

The following communication has been issued to the medical press by the Ministry of Health:

Wartime difficulties of production and wartime claims on skilled professional staff have made it impossible rapidly to develop schemes for the general use of mass radiography throughout the country. It is possible that employers or other persons may be considering whether they should not make their own arrangements for the examination of their employees or patients by mass miniature radiography. There are, however, complications and dangers, perhaps not immediately obvious, involved in any departure at present from the standard methods of the official scheme. These difficulties ought to be generally recognized.

The primary purpose of mass radiography is not diagnosis in the ordinary sense. Its true function is to discover in a group of ostensibly healthy persons those who have signs indicating the possibility of incipient disease, which should therefore be further investigated by more intensive means of diagnosis. Persons who have no ground to suspect that they are in any risk of illness must be ready to be examined. Anything that might weaken public confidence in mass radiography would therefore impair its usefulness. Equally anything that would lead the public to expect too much from the new development must be avoided.

The Medical Research Council's Committee on Tuberculosis in Wartime advocated in its report (Sept., 1942) that the use of mass radiography apparatus should be under the general direction of the Ministry of Health and Department of Health for Scotland. That committee's technical subcommittee said further: "Mass miniature radiography should not be lightly undertaken. A very high standard of quality of miniature radiography is necessary for correct interpretation, and the latter requires the highest radiological skill. The making-up of compromise apparatus cannot be too strongly condemned and would bring the method into disrepute."

The Mass Radiography Subcommittee of the Minister of Health's Standing Advisory Committee on Tuberculosis, in its report on the working of a mass radiography unit, said: "When mass miniature radiography is to be undertaken on a large scale, trustworthy and comparable results can be secured only with the use of a carefully designed standard apparatus."

In accordance with these authoritative views the Government has made certain that the standard apparatus which it has arranged to be manufactured, and supplied to selected local authorities, is of the highest standard and able to meet the much greater stresses to which such a unit is subject compared with ordinary x-ray machines, and so far as possible immune from mechanical breakdowns. Some breakdowns must occasionally occur, but those can be speedily dealt with by the operational teams specially trained by the Ministry of Health. This minimizes delay and consequent disturbance of production or routine when the unit is working in factories or offices.

Present experience has confirmed the soundness of the expert advice quoted. Any departure from the system by which the civilian population is examined by the standard apparatus and the methods laid down in the Advisory Committee's report on the working of a mass radiography unit must be strongly deprecated.

It is important to realize that mass radiography has not made the diagnosis of pulmonary tuberculosis easier; on the contrary, the method is bringing to light many symptomless minimal cases. Numbers of these recover spontaneously without treatment, and the prognosis in any given case can only be assessed by most careful clinical investigation and periodical supervision.

As a diagnosis of tuberculosis may involve change or loss of work for the individual, and may also prejudice his prospect in pension or life assurance schemes, it is essential that such a diagnosis, especially in minimal cases, should be undertaken only by those fully expert in tuberculosis, and with all the resources of up-to-date diagnostic procedures at their disposal. Full provision for this is made in the national scheme operated by the larger local health authorities as part of their tuberculosis service on the standardized lines recognized and recommended by the Ministry of Health and the Department of Health for Scotland.

There is another important consideration. The Government's mass radiography scheme includes arrangements for collecting far more information on the incidence of tuberculosis than has ever been available before. This will be of the greatest value in the campaign against this disease. The collection of this new evidence in the fullest measure can only be assured through a uniform scheme and a standardized system of records. Mass radiography activities carried out independently of the national scheme, and by other than standard apparatus and methods, cannot help this object and might, indeed, seriously prejudice it.

Ministry of Health,

Aug. 24, 1944.

Correspondence

Wound Fractures in Plaster-of-Paris

SIR.—As regional surgical adviser of a Ministry of Health Region I have been very much struck, when going round the surgical wards of E.M.S. hospitals to see the casualties arriving from Normandy, by an anxiety which is universal among surgeons in charge of cases of limb compound fractures sealed up in plaster-of-Paris. Most of these patients retain their original plaster covering on admission. The surgeon often hesitates to disturb a plaster, even when there is a suspicion that a wound may be going wrong, for it is felt that if the plaster is removed, the bone ends may not be replaced in such a good position, and a local removal of a plaster casing is not practicable. The surgeons have expressed to me their feeling that, if only they had free access to the wound, local medication with ? penicillin could be applied should events prove that it was indicated. Several have indicated, "If only I could get down to the wound, put in a tube, and perhaps introduce penicillin I would feel happier."

To obviate this anxiety could I commend to the notice of surgeons in our forward and base hospitals my routine practice in applying plaster-of-Paris bandages to any limb where there is a wound? Before the plaster is put on I fix a large pad of wool over the wound to indicate the exact site and the limits of the wound: the applied plaster hardens and a "blister" or "protuberance" is formed. If necessary this plaster blister can be removed in order to expose the wound area without disturbing the continuity of the plaster. The wound can then be dressed as required or have any form of local treatment.

Without reasonable facilities it may not be an easy matter to remove a plaster casing; to remove the "blister" or "protuberance" when indicated during transit of the patient on landing craft, hospital ship, ambulance, hospital train, etc., is an easy matter, for the blister can be removed by any form of saw. Such indications may be haemorrhage, gas gangrene, or other infective agencies.—I am, etc.,

Newcastle-upon-Tyne.

R. J. WILLAN.

War Malaria and its Treatment

SIR.—Malaria is an invariable companion of war, though to many medical officers in the Forces, E.M.S. doctors, and civilian practitioners it constitutes a new problem, and one for which they are not prepared either by experience or by study. Hence there is at the present time some confusion, which has manifested in a spate of papers and a number of letters in your correspondence columns. As in the last great war, there is a tendency to regard it almost as a new disease.

Subtertian (or malignant) and benign tertian malaria are really two entirely different entities, distinguished from one another not only by the morphological peculiarities of the parasites, but by their life-history, pathological and biochemical changes, clinical course, and reactions to treatments.

The subtertian (*Plasmodium falciparum*) is more a tropical and subtropical parasite, requiring a higher degree of temperature to complete its development, in the mosquito. The clinical pictures which it may evoke are extremely varied, and depend in their severity on the immunity of the patient to the infection. In the immune African, for instance, an attack of subtertian malaria is usually a trivial affair, but in the non-immune and therefore susceptible British and American soldiers and sailors it may be extremely severe. Cerebral cases are by no means infrequent, and the many complications include blackwater fever. In subtertian malaria the typical "ague fit" of the textbooks is usually absent, so that this fever may mimic many other diseases, thereby providing a trap for the unwary. There are other characteristics, such as the tendency to spontaneous recovery, more rapid development of immunity and therefore a lessened tendency to relapse, especially in temperate climates, and the more immediate effectiveness of quinine and mepacrine. The life-span of the parasites of any individual infection is comparatively short, lasting from nine months to one year. Enlargement of the spleen is not usually demonstrable in primary infections. Benign tertian malaria, on the other hand, is found throughout the Tropics and subtropics, and has an extensive range in temperate zones. It is therefore the predominant form of infection in the Mediterranean area and N. Africa, and is especially common in S. Italy and Sicily; and, as has been abundantly proved in this war, it is by no

jeans exceptional in the Congo and in W. Africa, where it was formerly thought to be rare.

P. vivax seldom, if ever, produces alarming symptoms or causes death. From the military point of view its importance lies in its nuisance value, apparent resistance in wartime to textbook treatment, and its great liability to relapse again and again. In those primary infections which are now occurring in soldiers returning from the Mediterranean the latent period may be prolonged to three months, or even as long as one year, till the malaria declares itself. The degree of anaemia produced is slight, but the splenic enlargement is usually more marked than in the subtertian, while the general health between relapses is good. In civil life relapses are regarded merely as a temporary inconvenience and hardly any justification for prolonged stay in hospital. Benign tertian certainly possesses a tendency to seasonal recurrence, and European infections are liable to relapse in spring, early summer, and autumn. This parasite is particularly persistent, and may survive in the body and produce relapses (outside the endemic area) for two to three years. Cerebral and other severe syndromes are unknown, and although the parasites disappear from the peripheral blood with quinine treatment, this drug does not entirely extirpate them, so that in heavily infected individuals these disappointing relapses are apt to occur.

Have for more than ten years thought and taught that mepacrine (mepacrin) possesses little of the virtue in the treatment of benign tertian which it undoubtedly has in subtertian.

As the treatment of malaria is again, as under similar circumstances a quarter of a century ago, being severely criticized, what, then, is the best course to pursue? We can dismiss subtertian malaria, as it presents no real therapeutic problem, being amenable to quinine and mepacrine. Indeed, the latter may be considered specific for *P. falciparum*. Pamaquin (plasmoquine) to my mind has no place in the treatment of the average subtertian case.

In benign tertian malaria the parasites disappear from the blood using quinine treatment if the drug is being absorbed. But when arasitic relapses occur during adequate quinine therapy I feel convinced either that the patient is not taking his quinine or that it is being given in an insoluble form, which has been shown to occur in the case of hard sugar-coated tablets. In these instances the Tanquet reaction should be employed to prove that this is so.

From the clinical angle the therapeutic action of quinine is more effective by injection, and this method certainly puts an end to the ever for the time being. At present there exists some prejudice against intramuscular quinine. It is argued that the injections are painful, cause muscular necrosis, and may even be dangerous. It may well be that some of the bad results which occurred in the past were due to abuse of this method and the acidity of the quinine preparation. When in a neutral isotonic solution of pH 7.2, as in solvolchlin, the injections are practically painless and not followed by ascertainable local reaction. A daily course of injections (6 or more) serves to control otherwise refractory infections and to some extent to prevent relapses. It is necessary to continue with small doses of quinine by the mouth—10 to 15 gr. daily—for three weeks or longer. I certainly believe that small doses of pamaquin—0.04 g. daily—in addition to quinine, also aid in preventing relapses. This line of treatment is effective in most peace-time cases in this country. The official course of quinine (30 gr. daily) for two days, mepacrine (0.3 g.) for five days, following by pamaquin (0.03 g. daily) for a similar period, appears to be inadequate. In addition to drug treatment there is the general nutrition to be attended to. Exertion, exposure, and fatigue undoubtedly predispose to relapse. Though this is well known, these three factors cannot be avoided, but as the malaria-infected Mediterranean is left behind it is safe to predict that less will be heard of benign tertian malaria or of relapses in soldiers returning to this country.

Your columns have recently contained much information about cerebral malaria. The well-documented case of I. B. Sneddon (1943) provided a basis for discussion. There the correct diagnosis was made and the case treated primarily on approved lines; but death was probably due, as had been frequently described, to subcortical haemorrhages. It may well be that retinal haemorrhages as disclosed by ophthalmoscopy may prove to be an indication of what is taking place inside the brain. There is also inadequate information on the cerebrospinal fluid in cerebral malaria, which may afford but little indication of the extent of the cerebral lesion. Usually it is found to be under pressure, and a pleocytosis has been noted.

J. M. Rogan (1944) has done a distinct service in formulating precise instructions for intravenous quinine, as regards both initial dosage and subsequent therapy. In the dozen cases of cerebral malaria that I have treated in this country during the last three years not more than 20 gr. of quinine dihydrochloride was necessary to restore the patients to full consciousness; but during the last war I saw fatal results from more massive initial doses of intravenous quinine (i.e., 30 gr.), and I feel

certain that it is sound to lay stress on the importance of the speed factor (2–4 minutes per grain). Intravenous pentothal, as advised by J. A. Gillett (1944), is certainly good treatment in cases which exhibit signs of cerebral irritation. Prof. W. I. Gerrard (1944) praises intramuscular atebirin (mepacrine) in pernicious malaria; but there is some reason to believe that in cerebral malaria it does not act as quickly on the parasites as does quinine, for I have had experience of one case of malarial coma from W. Africa which was quite unaffected by injection of atebirin musonate (0.3 gr.) but responded instantly to intravenous quinine dihydrochloride. Again, intramuscular atebirin may occasionally produce abscesses, and F. Hawking (1944) has recently shown that injection of therapeutic doses produces necrosis of the tissues, as with quinine, around the site.

It is surprising to read of Dr. Fenton-Russell's dread of psychological disturbances and the need for psychological treatment in all cases of cerebral malaria. It is true that abnormal mental states may ensue as the result of all forms of malaria, but it still remains a surprising fact how little cerebral disturbance is produced on recovery from cerebral malaria. Usually recovery, mental and physical, is complete. His memory does not serve him aright in suggesting that the quartan parasite may be responsible for cerebral complications. This misconception may have been based on the morphology of the parasite, as developing trophozoites of *P. falciparum* closely resemble those of *P. malariae*.—I am, etc.,

Haemolytic Streptococci and Scarlet Fever

SIR.—Describing an "explosive" outbreak of tonsillitis due to *Str. pyogenes* in your issue of Aug. 26 (p. 275), Fl. L. Lieut. Wilson "suggests that haemolytic streptococci belonging to subtype 9 play no part in the causation of scarlet fever." This generalization is based on rather thin premises. I can assure Fl. Lieut. Wilson that, while *Str. pyogenes* Type 9 is not one of the types commonly associated with scarlet fever in this country at present, it can give rise to the complete clinical picture of the disease. I have isolated from the throats of scarlet fever patients in London in the acute stage of illness haemolytic streptococci belonging to every one of the Griffith Types 1 to 30 except Type 18 and those not belonging to Group A (Types 7, 16, 20, and 21). Some of the types, such as Type 10 (Dochez) and Type 26, are extremely rarely met with in this country as a cause of either scarlet fever or tonsillitis, while others, such as Types 5, 13, 19, 23, 24, and 26, are uncommon. A table of the distribution of serological types among haemolytic streptococci from cases of scarlet fever in various countries of the world, including England up to 1938, is given by F. F. Schwenker *et al.* (*Amer. J. Hyg.*, 1943, 38, 27), and this shows clearly that all the Griffith types belonging to Group A Lancefield have been isolated from cases of scarlet fever.

The clinical picture of scarlet fever is in the main the resultant of two opposite and variable factors—the ability of the infecting strain to produce erythrogenic toxin and the presence of antitoxin in the system of the person attacked. *Str. pyogenes* Type 1 is one of the types most commonly found in this country as a cause of scarlet fever, and is not infrequently associated with local epidemic prevalence; it usually produces a potent erythrogenic toxin, but my late colleague, Dr. F. Griffith, and I have isolated from the throats of cases of acute tonsillitis strains of Type 1 which were incapable of producing erythrogenic toxin, and therefore unable to produce the rash of scarlet fever in susceptible subjects. The other factors, apart from erythrogenic toxin and antitoxin, influencing infection with *Str. pyogenes* are what, for lack of better knowledge, we call the invasive power of the organism and the resistance of the individual. The permutations and combinations of these factors, together with the portal of entry of infection, afford a rational explanation of the protean manifestations of infection with *Str. pyogenes*.

There is a school of thought which believes that the erythrotoxic toxins produced by different types of *Str. pyogenes* differ qualitatively as well as quantitatively, but that they may show a considerable degree of antigenic overlap. Some support for this view has been adduced, and some years ago Julia Coffey in the U.S.A. claimed to have obtained erythrotoxic toxins from four types of *Str. pyogenes*, which when combined covered the whole known gamut of toxin antigenicity; the Dochez strain (Type 10) and the Dick strain (Type 3) of *Str. pyogenes*, in common use for the production of Dick test toxin, are believed to possess a wide antigenic range.

I wonder why Fl. Lieut. Wilson uses the term "subtype" as distinct from "type." We know now that certain strains may possess specific antigens in common, such as Types 4 and 24, and Types 8 and 25, but we do not yet call them subtypes. *Str. pyogenes* Type 9 is a Group A (Lancefield) Type 9 (Griffith) haemolytic streptococcus. The differentiation of the antigens of Group A haemolytic streptococci is still in the melting-pot, and it is wise at present to keep the nomenclature as simple as possible.—I am, etc.,

London, S.W.1.

V. D. ALLISON.

Surgery in the Field

SIR.—General Mitchiner in his "Thoughts on Four Years of War Surgery" (July 8, p. 37) says that he "cannot help feeling that . . . progress is not so great as one would like to believe, especially in the prevention and control of sepsis; for the number of limbless patients landing from the Middle East and North Africa is by no means negligible." I would like to point out that sepsis is by no means the main reason for amputation. A number of amputations have been done for the specialized infection of gas gangrene, and a few for pyogenic infections of the knee-joint and the joints of the foot and ankle which were endangering the life of the patient. The main indications for amputation are gross lesions of main nerves and blood vessels, and in many instances shattering of the feet and legs from mine injuries.

Having seen surgery in France (1939–40), North Africa, Sicily, and Italy, I can say that I have never met the suggestions of "halting or feeling complacent" to which General Mitchiner refers. On the other hand, the surgeons in the field have been most enthusiastic in investigating and trying out new methods, new drugs, or new combinations of drugs. Research and investigation have been and are being carried out under the most difficult conditions. Also the question of early and adequate treatment for the lightly wounded has received much attention. Thousands of secondary and delayed primary sutures have been carried out, and this is a matter which is receiving special attention at the present time.

The investigations of the penicillin team, the shock team, the establishment of centres for vascular injuries, and the work done by the M.R.C. teams on burns and casualties in armoured vehicles, are all proofs of the continued efforts for the improvement of the condition of the wounded.—I am, etc.,

London, S.W.1

J. M. WEDDELL.

Riboflavin and Allied Deficiencies

SIR.—I have read with interest the abridged Lumleian Lectures in the *Journal* of July 22 and 29. Dr. Stannus describes a syndrome of epithelial and nervous lesions, referring to his early observations on pellagra in Nyasaland. He considers his observations important, saying it was the first time attention had been drawn to this syndrome, due to a dietetic deficiency dissociated from pellagra. Strachan (1897) did not mention pellagra and described a similar syndrome. He treated his patients for malaria, but found they all required a liberal diet. Stannus (1913) showed that maize was not a causative factor of the syndrome but gave no treatment. Scott (1918) described the syndrome but found contraindications to its being a new deficiency disease.

Stannus, in his lectures, gives credit to Fitzgerald Moore for "recognizing that the disease which was rendering thousands of natives nearly blind was due to a dietetic deficiency." I published a paper (1928) entitled "Diseases due to A and B Avitaminosis in Sierra Leone" in which I described the

epithelial and nervous lesions of the syndrome, and while dealing with defective vision recorded that "in the case of school children it is usually failure of vision that causes the child to be brought for treatment, a symptom which is so amenable to treatment if detected early enough," and went on to say "The essential treatment of the disease is to supply the vitamin deficiency . . . cod-liver oil and marmite were used to supplement the diet . . . marmite was used as a source of vitamin B." Fitzgerald Moore (1934), who so far had only described the epithelial lesions of the syndrome while paying particular attention to the defective vision, wrote: "Wright introduced in Sierra Leone a treatment for his cases before I did the same in Nigeria."

Stannus, in these published Lumleian Lectures, gives a table showing "Manifestations of the syndrome according to various authors"; in this he omits my record of 'ulval affection and conjunctivitis. In the manifestations of his own description of the syndrome he includes visual defect, which is a most important symptom. A perusal of Stannus's (1913) paper shows only five patients with vision defect out of 131—surely insufficient to warrant its inclusion in his syndrome. On the other hand he describes in his early work a skin condition complicating the syndrome 19 times among the 131 cases. His description of this skin complication, given in 1911 when he saw it 10 times among 40 cases, is a perfect picture of dermal evidence of vitamin A lack. This skin condition should be recorded as a part of the syndrome he described. It seems likely, in view of the diet these prisoner patients received, that Stannus was dealing with a deficiency state due to lack of both vitamins A and B. Although red palm oil (rich in carotene) and ground nuts (rich in riboflavin) are found in abundance in some tropical areas, their distribution is limited, and they are not necessarily prepared properly or eaten in adequate quantities. It is noteworthy that riboflavin, although widely distributed in food, is found abundantly in protective foods—milk, cheese, eggs, and green vegetables. It follows that in some areas the double deficiency is liable to arise. It should further be noted that both vitamin A and riboflavin are concerned with the maintenance of healthy epithelium; a lack of either may result in keratinization, but the tendency to inflammation and ulceration is less marked in vitamin A lack.

Stannus (1930), in a paper which was a lengthy criticism of my article (1928), wrote that he had very little hesitation in calling the disease I described pellagra. I have never agreed that it is pellagra, and defined the condition (1930) as "a disease distinct from pellagra and beriberi, characterized by lesions of the mucous membranes and skin especially evident at the mucocutaneous junctions, associated with or followed by disorders of the nervous system and curable by the addition of cod-liver oil and yeast to the diet."—I am, etc.,

Scurvy

SIR.—In their comprehensive survey of 53 cases of scurvy seen in Edinburgh between 1937 and 1944 McMillan and Inglis (Aug. 19, p. 233) found a peak incidence in 1941–2. My own experience of the incidence of scurvy in London differs. Working in L.C.C. hospitals and looking out for scurvy I saw only one case of frank scurvy a year from 1938 to 1942. But in 1943 I saw 7 personal cases (at one hospital), and in 1944 so far I have seen 9 cases. All the recent patients have been old-age pensioners. Difficulties in shopping and worry over the fate of relations have led to self-neglect, and made it easier for the pensioners to become scorbutic. None the less, most pensioners seen here show no evidence of scurvy, either clinically or on investigation of ascorbic acid levels. Prunty and Vass (*Lancet*, 1944, 1, 180) found no increase in the incidence of scurvy in London up to spring, 1943. It might be of interest and value to find the reason for the differing peak incidence.—I am, etc.,

London, E.3.

ELI DAVIS.

Bleeding Gums and Scurvy

SIR.—The clinical observations and arguments of Drs. Stamm, Macrae, and Yudkin (Aug. 19, p. 239) are doubtless of the greatest value, but they do not appear to be able to understand plain English. Thus on page 104 of *A Treatise of the Scurvy* Lind writes: "The first remark to make upon this disease is that whatever former complaint the patient has had, or whatever present disorder he labours under, upon being afflicted with the scurvy his old complaints are renewed and are present rendered worse." On page 101, writing of the symptoms, Lind says, "but a diversity is sometimes observed in the order of their appearance, thus when a person has had a preceding fever or tedious fit of sickness by which he has been much exhausted, the gums for the most part are first affected." On page 275, describing scurvy in Hampshire, Lind says, "The gums of several bled, being sore and spongy, without their having any other symptom of the scurvy. One person was greatly alarmed with a spitting of the blood for three days, which I found to be no more than scurvy affecting his gums." On page 242 Mr. Poupert describes the post-mortem examinations of scorbutic bodies. "We have seen several who without pain dropped down dead. They had no apparent sickness, only their gums were ulcerated, without any spots or hardness on their skin: yet we found their muscles were mortified and stuffed with a black corrupted blood."

Besides misquoting Lind, Drs. Stamm, Macrae, and Yudkin mention my name. I wish they would read a little more carefully the paper to which they refer. The term "bleeding gums" can hardly be applied to the condition described therein, and Roff and I made no inferences regarding "bleeding gums." Moreover, the subjects consisted of boys drawn from the depressed industrial areas of 1937. Their meagre vitamin C intake of 10 to 15 mg. per boy daily was rendered even more precarious by the fact that they were overcrowded together in a damp, cold climate and exposed to a virulent streptococcal infection. This is a state of affairs not comparable to the conditions of Drs. Stamm, Macrae, and Yudkin's experiment, and they should consider these differences before indulging in theories as to the explanation of the "apparent success of ascorbic acid."

There are many causes of gingivitis, and vitamin C will not help this condition unless the dietetic intake has been insufficient, when it acts by accelerating healing. I should say that an intake varying from 16.8 mg. to 26.8 mg. per day was probably sufficient for a healthy adult male not living in exposed conditions. Unfortunately some individuals in this country get less. In assessing the adequacy of a diet it must also be considered that individuals vary greatly in their requirements of vitamin C, and that differing conditions alter the requirements of any one individual. Thus all interested in vitamin C should first of all study Lind's classic work. They will gain more from it than from the consideration of Crandon's experiment.

The survey of scurvy by Drs. McMillan and Inglis (Aug. 19, p. 233) is valuable and timely, drawing attention as it does to the usefulness of the Ministry of Food's propaganda. I hope they will forgive me if I recommend them to read Lind, too. They will find that pain in the back is not such an unusual symptom of scurvy as they believe.—I am, etc.,

Episiotomy

SIR.—I think it is a great pity that Dr. H. S. Gaskell was not told by the lecturer at the postgraduate course which he attended in 1939 of the method and usefulness of suturing a torn perineum (or episiotomy) under local anaesthesia. It is obvious that when the patient is under a general anaesthetic there should be no hesitation in inserting the necessary sutures while she is still anaesthetized and before the placenta is expelled. Presumably Dr. Gaskell has on occasions been called by the district nurse to repair a torn perineum, and because he would never dream of giving a woman chloroform after the birth for the sole purpose of stitching her perineum,

he relies on a skilled hand and a sharp needle as his anaesthetics. My sympathies are with the unfortunate woman, who has just completed several hours of labour, a condition hardly to be compared with the insertion of three deep sutures in a cut wrist of a "he-man."

I see no objection to giving a little chloroform—I and many others have given it hundreds of times—but in the last few years I have used a local anaesthetic. The technique is easy, and it can be performed in the dirtiest and darkest cottage, even with the light of a candle, and the patient's gratitude is the answer to its painless completion.

I have not had forty years of practice yet, but have attended a few thousand confinements both in practice and in hospital during the past twenty-odd years, and I still use chloroform as my anaesthetic of choice in private houses and nursing homes because it is useful and convenient, though dangerous.

Like Dr. Gaskell, many of the pundits (but not the majority) give pitocin in certain cases of uterine inertia. I don't like it, won't do it, and won't allow it to be done, even in hospital. I note also that Dr. Gaskell gives ergometrine sometimes before expulsion and sometimes after expulsion of the placenta. He says by so doing he has abolished the boggy of the post-partum haemorrhage. I wish I could believe this, even though I strongly disagree with the practice of giving pitocin or ergometrine before the placenta is expelled.

An episiotomy is indicated in many first confinements, particularly when forceps are applied, but to advise episiotomy in all primiparae is nonsense.—I am, etc.,

D. J. P. O'MEARA,

Hon. Gynaecologist and Obstetrician, West Suffolk Hospital

Cause and Treatment of Sinusitis

SIR.—In the *Journal* of March 25 (p. 431) is a report of a discussion at the Royal Society of Medicine on sinus trouble in children. To me, as a specialist in diseases of the ear, nose, and throat, the subject of "sinus disease" is an increasing enigma. In my early days as a specialist I accepted the term "sinusitis" and the theories of infection, lack of ventilation, etc., as being the cause thereof. I regarded the disease as a local condition with secondary effects upon the health of the patient, and surgical treatment appeared to be the rational procedure.

Experience over the years, observation of my own patients and the patients of others, and particularly the study of cases at a public hospital for sick children and at military hospitals, have developed a firm conviction that sinus disease is not a disease *sui generis*, it is a local manifestation of a general biochemical abnormality. Bronchiectasis is another manifestation or result of the same biochemical disorder. In the majority of cases of sinus disease and bronchial disease early symptoms are not observed, and possibly many cases resolve without being recognized and, of course, without special treatment. On the other hand, many become the subject of subsequent infection, and we have obvious bronchiectasis and genuine sinusitis. Many cases of sinus disease progress to an extreme degree without the obvious presence of pus. Polyps usually develop without the previous appearance of pus—that is to say, in the absence of frank infection. There are probably other manifestations of this constitutional disorder—such, perhaps, as migraine, vertigo—and my observations have led me to the conclusion that many psychological conditions, etc., are, in fact, the outcome of it. It is responsible for the phenomena of allergy. I do not know whether it is as common in Europe and other countries as it is in Australia.

In the discussion referred to Mr. S. E. Birdsall is reported as stating that "cure of sinusitis in children depended only on recognition of the disease. Ephedrine was very often successful." I am afraid he is a superoptimist. In all my years I have never seen a cure effected by ephedrine; I have seen temporary alleviation of symptoms, especially in the acute exacerbations, but never a cure of the chronic sinus disease by ephedrine or any similar preparation. Patience and perseverance in advice and guidance as to hygiene, food, etc., and appropriate surgical measures are, of course, sometimes followed by satisfactory results; proof of the satisfactory end-results is the acceptance of some of these former patients as members of air-crew in the R.A.A.F. and R.A.F.

At present I am inclined to the view that this class of disease is essentially dietary in origin. The dietary deficiency is not simple and goes back for generations. There is a definite familial character about these complaints. It would appear likely that our vaunted civilization is responsible for the destruction of food values. It is often stated that sinus disease seen in Australia differs much from that met with in the British Isles and is much more prevalent. One colleague suggests as a contributing cause of this difference the fact that a fish diet is much commoner in the British Isles than in Australia.

This brings me a step further. As honorary E.N.T. specialist to a hospital for sick children I have been faced with the great prevalence of "sinus disease" in young children. I have seen so frequently the hopeless results after ephedrine, etc., and surgical measures, the common disappointment following the surgically perfect removal of tonsils and adenoids, but my attention has been drawn to the fact that the parents of some children who had been kept on cod-liver oil and iron for a year or more were very pleased with the children's improvement. For many years cod-liver oil has had a reputation in "chests and colds."

I developed the idea that this "sinus disease" was connected with a deficiency of vitamin A, and for years have had an impression that it was somehow related to faulty calcium metabolism. For some nine months now I have been using an Australian preparation of vitamins A and D in comparatively large doses from 50,000 to 100,000 international units of A and 6,000 to 15,000 international units of D daily. When infection is obviously present I have used an aqueous solution of acriflavine (1 in 1,500) for nasal instillation. In addition to its strong antiseptic action acriflavine appears to have a mild and prolonged astringent action on the "sodden" mucosa. Occasional antral lavages are done in special cases, and very very rarely have I been reduced to more radical surgery. In spite of some unsatisfactory results the general impression I have gained is that this treatment is a distinct advance; some of the results have been so remarkable that I can hardly believe the evidence actually before me. Two such cases I have recently reported to the *Medical Journal of Australia*, otherwise they would have been included in this statement. In patients in whom this vitamin therapy appears to do good locally there is also a marked general improvement, cough is diminished, the patient's colour is improved, and there is general subjective and objective evidence of well-being.—I am, etc.,

Brisbane.

ERNEST CULPIN.

Observation in the Student's Training

SIR,—Even in times of paper shortage it may be permissible to give thanks. Dr. Ff. Roberts deserves our thanks. For many years I have taught postgraduate medical students the elements of statistical methods—namely, the calculation of death rates, standard deviations, coefficients of correlation, etc.—and at the end of the course there is a practical examination. It is quite common for a student to produce an answer which is arithmetically impossible—for instance, a coefficient of correlation greater than unity; or factually impossible—for instance, a death rate surpassing Goebbels's estimate of the effects of bombing London, or one wildly optimistic. His common sense is paralysed. He thinks, usually rightly, that he has applied the correct process and does not check his arithmetic, *not being moved by the absurdity of the result*.

Dr. Roberts's remedy is, he thinks, revolutionary; I should go further. I believe that if a young man or woman can prove that he or she is a trained and accurate observer in *any* field of natural knowledge he or she could be safely admitted to study medicine without any preclinical teaching at all. The technical knowledge such a student would not have can be acquired easily enough if he is a trained observer. That great naturalist, Arthur William Bacot, had never attended a course in biology or even possessed a modern microscope before, in middle life, he came to the Lister Institute. He was paid and deserved this compliment by an expert: "Bacot never sees what isn't there." Not many young people are Bacots, but there are a good many who *are* trained, self-trained, observers, who do not identify a flying bird or a moth on a tree either by

guessing or by inaccurate reminiscence of a description in book. These are the salt of the earth; I think they would make good statisticians and even better clinicians.—I am, etc

Loughton.

MAJOR GREENWOOD.

SIR,—The article by Dr. Ff. Roberts (Aug. 26, p. 284) on observation in the student's training I found to be quite entertaining as an instance of the popular fallacy "seeing is believing." His remark about "minds unclouded by erudition" making "shrewd observations" is an example of what one may term the positive side of the fallacy. Its negative aspect is illustrated by his reference to the "mental costiveness" of civilized youth exterminating his "rudimentary powers of observation." The conclusion which Dr. Roberts appears to invite us to make is that the untutored mind sees things as they are, while the vision of the erudite person tends to be blurred and confused.

Dr. Roberts entertains us with the story of a young practitioner who sent him a case of fractured scaphoid which he had mistaken for a Colles's fracture—thinking it had some resemblance to a dinner-fork. Truly shocking, but one wonders what "the highly developed powers of observation possessed by the primitive man" of Dr. Roberts's imagination would have made of it! It may be presumed that he at any rate would have no obsession about "dinner-fork" deformities.

Yet with all his drawbacks I should prefer to rely on the judgment of the civilized youth, and what he wants is more not less, civilizing to improve his thinking powers, and more erudition to clear his mind of its primitive fog. Unaided vision however acute or painstaking, is not enough. There were many observant naturalists before Darwin, but they observed their facts with less reflection. The accumulation of undigested fact is our present curse, which, it seems to me, would be only intensified by turning medical education, as Dr. Roberts suggests, into "a naturalistic study." Not more facts, however but better theorizing; a little less stress on the importance of observation and more on sound reasoning appears to me our chief need in education. Believing without seeing may indeed lead us into error, but seeing without some rational belief lead us nowhere.

In the excellent quotation with which Dr. Roberts closes his communication it is significant to note that Dickens, when describing a "fine fellow," gives two points to reflection and erudition and one only to observation.—I am, etc.,

Kingswood, Bristol.

P. T. MACDONALD.

Psychological Medicine and the Family Doctor

SIR,—Air Cdre. Gillespie's lecture (Aug. 26, p. 263) is full of the balanced judgment and shrewd common sense which all who know him have come to expect. I was, however, a little disappointed to find the balance rather unfairly weighted in one particular, although I know from many conversations that this must have been accidental. I refer to his remarks about operations performed in the mistaken belief that an organic cause exists when the condition is really psychogenic. The such cases occur none would deny, although, as Air Cdre. Gillespie states, the number is smaller than is sometimes supposed.

But what of the cases where an organic condition really is present and where absence of adequate physical examination or mistaken psychological enthusiasm leads to neglect of a perform what may be a life-saving operation? Patients with "broken hearts, angry fathers, sexual guilt, or depression of spirits" may still develop an appendicular abscess or carcinoma of the colon! Air Cdre. Gillespie's memory of the patient whose innocent appendix was removed is livened by the fact that he survived to "flaunt his gawdy dressing-gown before his nurses." My memory of a patient who underwent psychotherapy until the third day of faecal vomiting from a carcinoma coli has the less colourful but more final background of a coffin.

By all means let us recognize the importance of psychogenic manifestations, but at the same time let us preserve a balance, and remember not only the importance of the organic lesion but also the need to recognize it even when camouflaged among psychopathic foliage.—I am, etc.,

London, W.1.

E. G. SLESINGER.

The Coroner's Post-mortem

SIR—The epidemic of "planning" is spreading rapidly now the coroners, who have not shown any signs of desiring a change, are to be prevented with a plan. But the suggestions contained in the letter of Dr H B May and his colleagues (Aug 26, p 288) reveal no indication of any real comprehension of the scope of medico-legal work. There is no reason for assuming that the novelty of a proposal, even of one made in the year 1944, is any guarantee of its value. *Vivere fortes ante Agamemnona*.

The writers of the letter say, "We consider that coroners' post mortems should be carried out by the hospital pathologist in the area and not by general practitioners, but such pathologists should have had adequate experience and training in morbid anatomy and medico-legal work. Where a pathologist is carrying out coroner's work for a large area it will often be preferable for him to be wholly employed on this work." We are thus left to suppose that the choice lies between the hospital pathologist and the general practitioner, whereas, in fact, the coroner can call on any medical practitioner he thinks fit. This has many advantages of which the most obvious is that he can call on an independent pathologist to perform the necropsy in any case in which the relatives make a complaint against the hospital.

Most of the work done for coroners involves the simplest kind of morbid anatomy. Only in a very small proportion of cases is there any difficulty in determining the cause of death, and in a number at least equally small is the work related to the complexities of the criminal law. But many cases with which the coroner deals are of a kind to lead to litigation later, usually under the Workmen's Compensation Acts. Are we to believe, as Dr May and his friends imply, that the morbid anatomist even if he has a considerable experience of medico-legal work, is the best adviser in such matters? If I may be permitted to be as dogmatic as the writers of the letter (and *Quod gravis asseritur, gravis negatur*), I would say that he is obviously not.

A physician with a sound knowledge of pathology and experience of medico-legal work is commonly admitted to be the best person to elucidate the relationship between injury or disease and subsequent disability. And if the subsequent disability leads to death, there is no reason for supposing that the pure morbid anatomist would be the person most competent to investigate the chain of events leading to this termination. The Act of 1926 gave the coroners all the powers needed for employing the man they think most suitable, and to suggest that they are incapable of choosing aright without coercion is a baseless aspersion on their integrity or sense or on both. Or is it perhaps possible that the new suggestions are really intended to diminish the freedom of coroners in a world in which liberty is becoming *demode*?

I know that some coroners, misled by the fashion for specialism, employ only pathologists who devote their whole time to coroners' work, but that they are ill advised in doing so is surely patent. And coercion is not needed to make them see the error of their ways: they are as capable or seeing the point or an argument as are morbid anatomists. If, then, they come to agree with the view that the best plan is to employ a man with a rather wider outlook than that of many morbid anatomists they will doubtless do so.

I shall presumably suffer the same fate as Drs Heaney, Turner and Haler because it will be said that my remarks are "purely destructive criticism." I plead guilty, but would say that when proposals have nothing to commend them, criticism of them ought to be destructive—I am etc.

London W 1

A PINEY

Specialism

SIR—We learn that when Herodotus visited Egypt 300 years B.C. he found that country full of physicians, all specialists. If the public had its way that would soon be true of the medical profession here. The public, convinced of its own wisdom and inclined to ignore the teaching of the medical profession, might be advised to consider what bearing on the subject have the words of St Paul in his first epistle to the Corinthians. For as the body is one and hath many members,

and all the members of that one body, being members, are one body . . . If the foot shall say, because I am not the hand I am not of the body, is it not therefore of the body? And the eye cannot say unto the hand, I have no need of thee."

In the memorandum on national health service issued by King Edward's Hospital Fund for London—a most concise and admirable memorandum—it is stated (p 5, para 8) "The present tendency to divide medicine into a number of isolated departments must be critically considered. The various parts and systems of the body are connected with one another; they are not separate entities, and symptoms arising in one part may be due to or associated with disease in another. Medicine, like the individual, must be considered as a whole, and undue systematic segregation of patients according to their various diseases and conditions is to be avoided."

This point of view is probably accepted by the majority of thoughtful doctors, but nevertheless many excellent highly respected medical men and women are pressing for more specialization in their own particular fields of work—a very human failing of the expert apt to lay too much stress on the uncommon of which he sees far more than the average. The maternity service, industrial medicine, administration of anaesthetics—all these and an increasing number of other departments are to be staffed by specialists.

Undoubtedly in each of these departments specialists are necessary, but if medicine is to progress satisfactorily they should with the exception of the anaesthetist, act as consultants, and even in the case of anaesthetics more harm than good would come from restricting their administration to specialists. Obviously the medical curriculum is at fault if it cannot produce general practitioners competent to deal satisfactorily with all the common forms of disease and such other conditions as call for the presence of a doctor—such as childbirth. But it is essential that the general practitioner should recognize the limitations of his knowledge in the many fields his work necessarily ranges over and be ready to call in the consultant as soon as those limitations are reached. To produce a competent general practitioner the curriculum needs drastically pruning, so that important branches may develop satisfactorily and produce this much needed fruit. The desired result would be more quickly attained if students would bear in mind the saying of Sir Robert Hutchison "No one is too good to be a general practitioner."

One weakness of the White Paper on a National Health Service is that it envisages the general practitioner as subordinate to the consultant and specialist. Such a position is not satisfactory to either doctor or patient. Consultants and specialists are doing essential work, but the first line of defence is held by the general practitioners. If the general practitioner service is at present unsatisfactory it must be improved, but this will not be done by making the best, represented by the specialist, the enemy of the good, the general practitioner—I am, etc.

London W 8

HAROLD H SANGLETT

Service Medicine

SIR—As one who has been in addition to looking after my own private practice a "civilian medical practitioner" under contract in charge of an R A F station since its inception over four years ago and also more of an administrator than a clinician in the last war perhaps my experience may be helpful.

I am in charge of two wards—five beds in one for R A F, three beds in the other for W A A F personnel with one corporal medical orderly (R A F) and two W A A F medical orderlies. Officially patients are not allowed to remain in the wards for longer than 24 hours but unofficially one allows this when and where necessary. I take sick parade every morning inspect cookhouse etc and advise the C O when necessary on hygiene. Further I have given lectures on first aid and V D and am on tap for any emergencies. It will be appreciated then that I am, to all intents and purposes an M O without uniform. I serve of course under the immediate supervision of the Wing M O, but in some matters I am directly responsible to the S M O (Group).

In my opinion the advantages of the R A F Medical Service far outweigh those of civilian practice, and I am writing more from the point of view of the patient. (a) There is a complete

history sheet kept up to date since enlistment. (b) There is a plentiful supply of drugs; if there are any drugs which are neither held in stock nor at Wing H.Q. and for which one has a *penchant*, authority is given to obtain them by local purchase. (c) There are wards into which patients can be admitted for observation, investigation, and treatment. (d) Specialists are always available for any type of case, and, if urgent, appointments are expedited. (e) Paper work, to my mind the most irksome but very necessary part of the routine, is done by the medical orderlies, although this does not absolve one from ignorance of "orders." Here I think is the crux of the matter; the medical orderlies must know and do their part, and if they are efficient the medical branch of the station is efficient, and hence the medical service as a whole is efficient; it is up to the M.O. or C.M.P. to see that they are *au fait* with the regulations.

Maybe, under State insurance, if we doctors have someone to take off our shoulders the tedious writing, etc., which we have to do now in civil practice, we shall have more time to devote to the clinical aspect of medicine, as is definitely the case in Service medicine.—I am, etc.,

Norwich

P. B. CORBETT.

Social Background of the Future Doctor

SIR.—The recent medical questionnaires provide some interesting social information. They permit an estimate of how far the various strata of our society contribute their sons and daughters to the profession of medicine; and these relative contributions can be compared with the proportions of these strata in the general population (as judged from the census returns). In the following table the grouped percentages show the social origins of medical students and of doctors, on the basis of the occupations of their fathers. For comparison the estimated percentage distribution of approximately the same occupational groups in the general male population is given.

Occupation	Fathers of Students ¹	Fathers of Doctors ²	General Male Pop. (approx.) ³	R.-G.'s Social Classes
Medicine Company director, higher professions, Civil Service higher grades, independent	87	86	20	I and II
Salaried—clerical, salaried manager, teacher, proprietor, retail business, farmer				
Skilled artisan, clerical—weekly wages, shop assistant, Civil Service lower grades	6	5	80	III, IV and V
Others—weekly wages, factory, transport, mining, etc.				
No reply	7	9	—	
	100%	100%	100%	

¹ B.M.S.A. inquiry, *Supplement*, Aug. 19, p. 40.

² B.M.A. inquiry, provisional figures, by courtesy of B.I.P.O.

³ Registrar-General's Decennial Suppt., 1931, Pt. IIa. The figures are similar whether all males or husbands of married women are used.

Two conclusions emerge from this table. First, that roughly 20% of all families (the so-called upper and middle strata, including the professional classes) contribute between 80 and 90% of our doctors, while the remaining 80% or so of families (constituting what is often termed the working class and including most weekly wage-earners) contribute no more than about 5 or 6% of the profession. Secondly, that the proportional contribution of these two broad social groups in the present body of students is not materially different from that in the previous generations. Evidently we are very far from a position where we are recruiting into medicine all sections of the community proportionately. The Planning Committee of the Royal College of Physicians and the Goodenough Committee both stress the discriminating effects of financial disability in a long technical training. The former recommends free university education and the latter adequate grants throughout training, including maintenance provision. The Goodenough Committee considers that unsuitability should be the sole barrier to a medical career, and suggests that the newer scientific aptitude tests might assist in the selection. These are important and wise suggestions. In the post-war world surely no nation will be able to afford to neglect its intellectual resources by drawing

its doctors from a narrow and economically favoured section. On the contrary it will be necessary to develop the talent of every boy and girl, and give to each an equal opportunity, whether the father be professional man, manager, or manual worker.—I am, etc.,

London, W.1.

P. D'ARCY HART.

Freedom to Publish

SIR.—In your note under the above heading in the *Journal* of Aug. 12 (p. 219) you speak of appealing to the large employing authority in the country to treat its medical staff reasonably, and you call upon practitioners to bring pressure to bear at all points to protect their freedom to publish. I think this moderate and apologetic tone, now so frequently employed by the profession over medico-political questions, greatly to be deprecated. Is it not time that we became much more truculent and, in some directions, stated clearly what we will accept and what we will not accept from governing bodies and outside authorities generally, and by standing together get exactly what we want, becoming the hammer instead of the malleable metal for a change?—I am, etc.,

Cyril G. Eastwood,

Weston-super-Mare.

Medical Officer of Health.

Wooden German Bullets

SIR.—In the *Journal* of Feb. 6, 1943 (p. 170), I recorded the x-ray appearances of five types of bullets the German air force were loading in their machine-gun belts. By the courtesy of a Naval friend recently back from the fighting at Cherbourg I am able to show the x-ray appearances of a round of rifle ammunition with a wooden bullet instead of the customary metal variety. I am told that the Germans became hampered for ammunition at Cherbourg and resorted to the wooden bullet type of ammunition, which was found to be

effective up to about 100 yards. The present reproduction of a radiograph was made with the complete cartridge and bullet placed between a patient's leg and the film. The wooden bullet is practically invisible to x-rays. At a short range of 100 yards the wood breaks up on striking solid structures such as bone and the scattered fragments are not likely to be localized by radiological methods.—I am, etc.,

London, W.1.

NORMAN P. HENDERSON.

According to Raetig (*Dtsch. Militärarzt*, 1944, 9, 5) the erythrocyte sedimentation rate is remarkably low in typhus. In the first week of the disease it remains at the higher limits of normal and there after slowly rises. The low sedimentation rate is an important help for early diagnosis of typhus before the outbreak of the exanthem because in those diseases from which it should be differentiated the rate is high.

Obituary

SIR ARTHUR HURST

fellow pilgrim writes:

Although it was not my good fortune to know Arthur Hurst in the days of his greatest activity, I have had the privilege of his friendship now for a number of years. His was a rare and delightful personality. His gifts, which were truly remarkable, he used sparingly and with unflagging energy in the advancement of medical knowledge, in teaching and inspiring others in "the research and study of the secrets of Nature by way of experiment," and, in following the precepts of Harvey, in promoting "mutual love and affection among physicians." Hurst had the internationalism of medicine much at heart, and in 1928 led a small company of physicians on the first of a long series of annual pilgrimages to foreign medical schools. On these occasions he was seen at his best and happiest. An excellent linguist, he was familiar with the best Continental literature and the work of the best men. He was warmly welcomed wherever he went and gave many lectures on his own subject, using French or German with equal felicity. His fellow pilgrims will long treasure the memory of these delightful sittings under his leadership.

Hurst was no specialist, and his interests and many contributions to medical literature covered a wide range of subjects. Of gastroenterology he was an acknowledged master with a world-wide reputation, and his original studies of intestinal function by means of idiology, his work on visceral sensation, and his conception of an enteric diathesis, have laid the foundations of modern gastroenterology. He was largely instrumental in founding in 1937 the Gastroenterological Club of Great Britain and became its first president.

Great though his gifts were, and enduring as much of his work will be, it was his courage, his fortitude in overcoming the adversities of physical handicap and ill-health, which endeared him most to those who knew him best. No complaint ever fell from his lips. He accepted his burden and made light of it, so that even the recurrent episodes of infirmity were taken for granted. They seemed to spur him to ever greater efforts, and like Wordsworth's happy warrior, he "turned his necessity to glorious gain." But it had been only too evident of late that his strength was slowly failing. The evening before his death he was one of a small group of younger men, and, though gravely handicapped, dominated the company, as was his wont, with incisive comment and argument in a discussion as to the most important advances in medicine during recent years. In the morning he worked at an autobiography which he had long been writing, and the end came peacefully while he was engaged on his congenial task. Arthur Hurst died as he would have wished, his work, his fine intellect undiminished after a full life lived to much purpose. A great physician, a brilliant teacher, and a most lovable man, his death will occasion widespread sorrow, his life deep thankfulness.

Dr. Alex. Patton writes:

May I add a humble tribute to the memory of a great genius? In a world where so many able teachers fail to transmit even ideas of value, William Osler and Arthur Hurst—heard once only across the years—remain as an abiding beacon of charm and lucidity. So often a babel, and not only in Aesculapian counsel, the English language becomes in the hands of these rare spirits a beautiful instrument to clothe refulgent thought.

The death of DOUGLAS ASHLEY MITCHELL, M.D.Lond., F.R.C.S.Ed., as the result of a motor collision is little short of disastrous to Bath and district. He had worked as specialist obstetrician and gynaecologist since 1930, when a special obstetrical and gynaecological department was formed in the Royal United Hospital largely as the result of his enterprise and enthusiasm. Two years later arrangements were made for the city maternity hospital service to be centred in the Royal United Hospital under the general direction of Mitchell and his staff. During the last war Douglas Mitchell served with the Royal Navy, retiring with the rank of lieutenant-commander, and then took up general practice at Midsomer Norton. He soon found his special interest and moved to Bath. A member of the B.M.A. since 1911, he served as chairman of the Bath Division during 1936-7. He was elected to Membership of the Royal College of Obstetricians and Gynaecologists in 1933 and was the author of several articles in the medical journals. He made himself universally beloved by all his colleagues and by a large circle of patients, and his loss will be mourned throughout the district as that of a close personal friend.—R. G. G.

We regret to record the death by enemy action of DR. LUTHER JAMES SOUTTER. His eldest son, Ian, a medical student, was killed on the same occasion, and his wife was

injured. Dr. Soutter was born on Dec. 13, 1898, the son and grandson of doctors. From Tollington School he entered Westminster Hospital with a scholarship, and won several prizes on his way to graduating M.B., B.S.Lond. in 1922. After working as house-physician and house-surgeon at the Westminster he took over his father's practice at Highbury and quickly gained the regard and admiration of his patients. In addition to his many professional duties he played a prominent part in A.R.P. work in the borough of Hornsey, where he was medical officer of a mobile unit; he will be sadly missed among the Civil Defence personnel of the borough. A congregation of some 700 colleagues, friends, and patients attended the funeral service at Highbury Quadrant Church. Dr. G. F. Rigden, Hornsey A.R.P. medical officer, in a high tribute paid to his colleague in the local newspaper, has written: "The Hornsey mobile units, largely owing to Dr. Soutter's energy and foresight, were pioneers at working at the incident immediately after it occurred, work which was not their original function but which has now been generally adopted and recognized as invaluable."

News has reached this country of the death on June 25 in Victoria, British Columbia, of Dr. IVAN WILLIAM MACKINNON, who had been a member of the B.M.A. since the year in which the Association held its Annual Meeting at Winnipeg. Dr. MacKinnon studied medicine in Montreal and Edinburgh; he graduated M.D., C.M. of McGill University in 1902 and took the Scottish triple qualification in 1906. He had been house-physician to the Royal Victoria Hospital, Montreal, and house-surgeon and senior clinical assistant to the London Throat Hospital; and during the last war he served with the rank of captain, R.A.M.C. (T.). For some little time before the present war he had made voyages as a ship surgeon.

The Services

Temp Surg. Lieut. A. Finlayson, R.N.V.R., has been mentioned in dispatches for great skill and devotion to duty in the care of survivors from ships which were sunk on the hazardous passage to North Russia.

Temp. Surg. Lieut. E. Fowler, R.N.V.R., has been mentioned in dispatches. This name appears in a list of awards for outstanding courage, skill and devotion to duty in certain of H.M. ships in action with German destroyers.

Acting Wing Cmdr R. H. Winfield, A.F.C., R.A.F.O., has been awarded the D.F.C. in recognition of gallantry and devotion to duty in the execution of air operations.

Capt. (Temp. Major) J. G. Reid, R.A.M.C., has been appointed M.V.O. (Fourth Class).

The London Gazette has announced the following appointments, awards, and mentions in recognition of gallant and distinguished services in Italy.

C.B.E. (Military Division).—Brig. (Temp.) S. Arnott, D.S.O., late R.A.M.C.; Lieut.-Col. (acting Col.) C. H. Playfair, O.B.E., R.C.A.M.C.

O.B.E. (Military Division).—Col. E. C. Beddows, M.C., late R.A.M.C.; Col. (Acting) J. W. Hirst, T.D.; Col. (Temp.) C. E. Eccles; Lieut.-Col. F. A. Roddy; Majors (Temp. Lieut.-Cols.) W. C. Alford, R. Armstrong, J. A. Binning, G. W. Crammin, A. L. d'Abreu, I. D. Easton, C. D. Evans, J. L. Gordon, F. H. Hollingshead, A. M. Hughes, M.C.; T.D.; W. H. M. Jones, T.D.; F. P. L. Lander, W. D. F. Lytle, A. S. Pern, T.D.; R. W. Scott, E. J. Selby, R. W. D. Turner, and R. B. Wright, R.A.M.C.; Lieut.-Col. R. C. Dickson, R.C.A.M.C.

M.B.E. (Military Division).—Capt. (Temp. Major) J. B. Barr, W. R. West-Watson, G. Blackburn, C. D. P. Jones, R. Kauntze, D. G. Liversidge; Capt. G. H. M. Hemsted, A. Henderson, and A. E. O'Donnell, R.A.M.C.; Capt. M. S. R. Rao, I.A.M.C.

D.S.O.—Capt. (Temp. Major) F. J. O'Dowd, I.A.M.C.

M.C.—Capt. J. G. Macarthur, R. J. N. Fellow, W. H. Lang, T. McCarroll, and L. J. Samuels; Lieut. F. H. Leckie, and T. Notman, R.A.M.C.; Capt. F. Martin, R.C.A.M.C.; Capt. H. L. Bhatia, I.A.M.C.

Mentioned in Dispatches.—Major-Gen. (Acting) R. W. Galloway, C.B.E., D.S.O.; Brig. (Temp.) W. P. Croker; Majors (Temp. Lieut.-Cols.) W. C. Alford, H. Allan, M.C.; W. M. Capper, R. W. Hendry, and D. T. Swift; Capt. (Temp. Major) J. W. L. Bain, H. J. Bell, H. W. Burge, D. J. Campbell, S. Carter, H. J. Croghan, V. Downie, M.C.; P. R. Evans, T. D. W. Fryer, C. C. Hurst, J. Irvine, D. B. Jagger, T. G. S. James, J. G. Jamieson, J. W. Litchfield, R. B. Robertson, M.B.E.; J. McL. Ross, C. V. Salisbury, V. A. J. Swain, N. G. G. Talbot, E. Townsend, M.C.; W. S. Tulloch, and R. H. Webber; Capt. K. M. Bell, A. M. Brown, N. C. Coombs, F. H. Counihan, J. Cumming, J. S. Davidson, T. C. H. Davies, W. A. Dewar, F. R. Duggan, S. M. Gill, J. G. Gow, C. J. Hodson, H. J.

Holloway, C W Marshall, R D Rutherford, R W Temple, and H A Wells, Lieut R H Hughes, R A M C, Col G R D Farmer, Lieut-Col R W Richardson, Major D A Young, Capt C A Campbell, H V Slemmon, D A Wanklyn, R C A M C, Acting Subadar-Major K L Sharma, I A M C

The *London Gazette* has announced the following awards in recognition of gallant and distinguished services in Normandy

D S O—Majors (Temp Lieut-Cols) D M Ahern and E I B Harvey, and Capt (Temp Major) A D Young, R A M C

Bar to the M C—Capt (Temp Major) P K Jenkins, M C, R A M C

M C—Capt (Acting Major) L V MacDonald, Capt G R Clark, J C F Cregan (attached Special Service Troops), W R Lamb, G P McGowan, J C R Nuttall-Smith, G S Sheill, P H Tasker (attached Special Service Troops), J C Thom (since killed in action), D J Tibbs, W W Yellowlees, Lieuts G M Ashurst, D M de R Wanser (attached Special Service Troops), R A M C

The following awards have been announced in recognition of gallant and distinguished services in the field

D S O—Major H A Procter, R C A M C

M C—Capt L E Cowan and J A Patterson, Lieut J L Heaslip, R C A M C

CASUALTIES IN THE MEDICAL SERVICES

Major EWAN BOILEAU ROTHERHAM, son of Dr and Mrs F H Rotherham of Grimsby was born April 27, 1907. From Uppingham he went to the London Hospital, qualified in 1932, and took the M B, B S Lond in 1933 with honours and distinction in obstetrics and gynaecology, after which he practised at Grimsby. He volunteered at the outbreak of war and went to France in February, 1940. He was through Dunkirk, and went over-seas again in May, 1942, being promoted to major six months later. He was reported on April 26, 1944, as lost at sea on Feb 12, 1944, and is now presumed killed in action. He was a member of the B M A, and before the war served on the local executive. Mr Guy Pulvertaft writes: "The news of Ewan Rotherham's loss at sea was a hard knock to those who knew and loved him, and it is difficult to express in words all that he meant to us. Ewan came from the London Hospital in 1933 to work in practice with his father and was soon recognized as a future leader among us. He was always well informed of recent work, and enriched his knowledge with a tenderness and devotion which was an inspiration to those who saw his work. Paediatrics held his keen interest, and his special gifts were gaining him a growing reputation. In early 1940 Ewan received his commission in the R A M C and in the Army he found his fullest expression. Those who were honoured by his friendship and saw him during brief periods of leave could not fail to be struck by his inward happiness and peace, seen only in those who have no fear of life. His friends mourn him and their hearts go out to his dear ones who face the future here without him."

Killed on active service in Normandy—Major F H Lloyd, R A M C

DEATHS IN THE SERVICES

Lt Col OWEN ALFRED ROWLAND BERKELEY-HILL, I M S, is reported to have died recently at Ranchi, India. He was the son of the well known University College Hospital surgeon and was educated at Oxford, Gottingen, and University College Hospital, London. He qualified with the London Conjoint Board in 1905, took his university degrees in the following year, the D T M in 1907, and proceeded M D Oxon in 1914. He gained the first place at the entrance examination for the I M S in 1907 and later specialized in mental diseases and psychology and became the leading authority on those subjects in India at a time when they had been much neglected. When it was decided to move the very out-of-date lunatic asylum from Calcutta, which had previously been a subordinate charge of the senior resident surgeon of the neighbouring European General Hospital, and to build a modern institution in the country near Ranchi in Chota Nagpur at an elevation of some 2,000 feet, Berkeley-Hill was chosen to organize and superintend it, which he did with characteristic thoroughness. Apart from war service in East Africa he spent the remainder of his time in the Ranchi post. After his retirement from the Service he lived in England for some years with his wife, an Indian lady, and several children, but subsequently returned to Ranchi to end his days there. His work in organizing the first modern mental institution will live after him, and he contributed a number of papers on his specialty to medical journals. Socially he was the wittiest of companions and a great talker. Officially he was difficult to deal with, but he was successful in his insistence on the new mental hospital being really up to date at whatever cost. It will be long before he is forgotten by those who knew him well.

Major P Heffernan, I M S (ret.), writes: "Endowed by Nature with a brilliant intellect, a needle-like wit, and an unsurpassed power of instantaneous repartee, as well as with a considerable amount of

congenital impishness, Berkeley-Hill laid himself out throughout his life to debunk pomposity and stupidity in high places, so that on more than one occasion both India and Africa became almost too hot to hold him. In his specialty he was far in advance of his time, and his contributions to scientific journals written years ago compare favourably with those of to-day's psychiatrists and are remarkably modern in outlook. His son, a pilot officer in the Royal Air Force, was killed in the defence of Malta two years ago."

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on July 29 the following medical degrees were conferred

M D—T B L Bryan
M B B Chir—T S L Beswick *D G Bratherton *D Brazier *G J Crockett *P D B Davies *P J De Vescoy *H J Dismore *J F Dudgeon *M A Floyer *P H Friedlander *J W Fullerton C E F Green *J A Harrington *C E Hartley *R F Hollick *N S Hooton *W R Horsfall *R E Irvine *W Kwanten *J Lorber *M B Matthews *J R May M Newton *K N V Palmer *M B Paul *P B Philip-Smith *P D G Pugh *G F Roberts *J Roche *B Schofield *J A Sherriff *J F N Siddons *C A Storr *J M Stowers *M Symons *P G Turner *D R D Vanstone *B H Vawdrey *D G Venter *P R Westall *V H Wilson *A P Wingate L Wolman *G S Yeoh

*By proxy

An announcement appears in the *University Reporter* inviting applications for the post of whole-time secretary of a committee appointed to arrange, on behalf of the Ministry of Health, for the provision of postgraduate instruction in the Eastern Counties for medical officers released from the Forces. Applicants should be graduates in medicine. The appointment is temporary and will be for one year in the first instance. The salary will not exceed £1,000 a year, non-pensionable, with an allowance for travelling expenses. Applications should be sent before Oct 2 to the Registrar, University Registry, Cambridge.

UNIVERSITY OF LIVERPOOL

As a result of collaboration between Liverpool University, the Liverpool City Council, and the Royal Liverpool Children's Hospital who will share the cost, a Department of Child Health has been established within the University and will be opened by the Minister of Health in the autumn.

Dr Norman B Capon, F R C P, has been appointed part-time director of the new department, and has been given the title of Professor of Child Health while holding that post. He has been lecturer in diseases of children in the University since 1935 and he is also a lecturer in clinical medicine. The new department will be concerned not only with the investigation of diseases of childhood, but also with the preservation of good health, physical and mental, during the early years of life. Its staff will consist of members of the staffs of Alder Hey Children's Hospital, belonging to the Liverpool Corporation, and of the Royal Liverpool Children's Hospital, and will include both full-time officers and part-time officers who, like Prof Capon, will combine private practice with their departmental duties.

UNIVERSITY OF GLASGOW

Dr Thomas Ferguson, deputy chief medical officer, Department of Health for Scotland, has been appointed to succeed Prof James M Mackintosh as Professor of Public Health in the University. The incumbent of this chair is associated with the work of the Corporation Public Health Department. Dr Ferguson graduated M B, Ch B Ed in 1922. He became a member of the Home Office Medical Board for Siltosis in 1929, and a year later was appointed H M Medical Inspector of Factories in Scotland with headquarters in Glasgow. He joined the staff of the Department of Health for Scotland in 1933.

SOCIETY OF APOTHECARIES OF LONDON

At a recent meeting of the Court of Assistants, with Mr L Vernon Cargill, Deputy Master, in the chair, Dr J P Hedley was elected Master for the ensuing year and Dr H F Powell and Dr C T Parsons, Wardens. Rear-Adm C P G Wakeley succeeded Sir Hugh Lett as the Society's representative on the Governing Body of the British Postgraduate Medical School, and Dr H Seaward Morley was appointed to represent the Society on the Negotiating Body of the British Medical Association. The Honorary Diploma of the Society was bestowed upon Sir Buckston Browne, LL D, F R C S.

The Diploma was granted upon examination to D Cappon E A Humphrey I W Williams L J Wood R W Barr-Brown K R J Coates N J Caldwell T H Eustace I P D W Skenpton A E Buck A H Pote

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Aug 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland. Figures of Births and Deaths in 14 principal towns in England and Wales (including London) (f) The 126 great towns in England and Wales (including London) (g) London (administrative county) (h) The 15 principal towns in Scotland (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or returns available.

Disease	1944					1943 (Corresponding Week)

Live births Annual rate per 1 000 persons living	6 406	496	941	325	25	5 589	703	866	370	245
Stillbirths Rate per 1 000 total births (including stillborn)	226	14	20	—	—	193	14	36	—	—

* Measles and whooping-cough are not notifiable in Scotland and the returns are therefore an approximation only.

† Includes primary forms for England and Wales, London (administrative county) and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evaluation schemes and other movements of population birth and death rates for Northern Ireland are not longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications for whooping cough were 1.9 higher than last week and for dysentery 121 higher. The incidence of measles and diphtheria fell by 189 and 35 respectively.

For the first time the notifications of diphtheria which is more prevalent in the north than in the south were fewer than 400. Only 13 of the 393 cases were recorded in the combined regions of London, south east, south west, south midlands, and eastern counties. There were local variations in the trend of whooping cough in the south east and south west there was a rise of 121 and in the west midland counties of 63, in the south midlands the notifications fell by 79. In the southern counties a fall of 139 was recorded for measles notifications.

The incidence of dysentery with a jump from 127 to 248 cases, has reverted to the high level of the first six months of the year. There were new outbreaks during the week in Cheshire 30, Durham 18, Essex 16, Leicestershire 14. The other principal centres of infection were Lancashire 3, Glamorganshire 14, London 14, Surrey 14.

In Scotland there was a rise in the notifications of diphtheria 29 and of dysentery 17, the latter being due mainly to the large increase from 24 to 47 reported from Glasgow. There was also a small increase in Edinburgh from 21 to 25.

In Eire the large rise of 81 in the notifications of diarrhoea and enteritis under the age of 2 was contributed by Dublin C.B. where there were 107 cases compared with 7 in the preceding week. The incidence of typhoid fell from 23 to 10.

Poliomyelitis in America

The incidence of poliomyelitis in the U.S. is at the highest level since 1916. Since the beginning of the year 3 311 cases have been reported, this being almost 1 000 more than in the same period of last year.

Week Ending August 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1 071, whooping cough 1 316, diphtheria 410, measles 1 114, acute pneumonia 321, cerebrospinal fever 30, acute poliomyelitis 25, dysentery 299, paratyphoid 14, typhoid 8.

Medical News

A sessional meeting of the Royal Sanitary Institute will be held at the Civic Offices, Swindon, on Saturday Sept. 30 at 10.30 a.m., under the chairmanship of Dr Thomas Orr, with Dr Llywelyn Roberts as honorary local secretary.

The Nuffield Provincial Hospitals Trust, on the recommendation of the standing committee of the Trust's Scottish Advisory Committee, have made a grant in aid of further research in neonatal and infant problems to be carried out by the Department of Child Life and Health of Edinburgh University at the Simpson Maternity Pavilion, Edinburgh. The grant which will be made for an initial experimental period of three years and will cover the appointment of a specially qualified nurse-expert and teacher, will allow a planned and detailed study of the important physiological problems of early nutrition and infant dietetics to be made. In addition to infant dietetics and particularly of breast feeding the problem of prematurity which plays a large part in infant mortality during the first month will be dealt with. The research will be directed by Prof. Charles McNeil and the experiment will be under the auspices of the University and the Royal Infirmary of Edinburgh. It is hoped that this research will have practical results which, when embodied in the teaching of medical students, pupil midwives, and pupil health visitors will raise the general standard of infant health and reduce infant mortality.

The Ministry of Health has issued a memorandum (Circular 106/44) concerning the use of mobile first aid units. The memorandum has been prepared in the light of practical experience of the operation of the units where they have been in use during raids. It should be of interest to all medical officers in the first aid post service, and the Minister desires that it should be made available to them. A sufficient number of copies for this purpose is being sent to the County Medical Officer or M.O.H.

The organizing committee of the Institution of Chemical Engineers has decided to postpone the joint conference on instruments for the automatic controlling and recording of chemical and other processes, which was to have been held in London on Sept. 22 and 23.

Repairing Torn Perineum

Mr M P REDDINGTON (London, W1) writes The directions given in "Any Questions?" (Aug 12, p 230) on how to repair a torn perineum cannot possibly be allowed. They state "To complete this small operation, a rectal examination is made to ensure that there has been no damage to the rectum." Presumably, if rectal damage is found, your instructor undoes his stitches, repairs the rectal damage, and repeats his perineal repairs. Again "An examination is made to ensure that no stitches have been inserted through the rectal mucosa." I presume he uses a cystoscope after a colporrhaphy "to ensure that no stitches have been inserted through the bladder." Really, Sir, English surgery must have a steadier hand than this. He advises mattress sutures to bring together the torn ends of the internal sphincter and. Mattress sutures should not be used in muscle. He further states that the vaginal mucosa should be sewn up before approximating the perineal tissues. If this is done, it is much easier to put in this topmost stitch when the vaginal wall has been sewn for about half its length. I see too that he advises silkworm-gut for the perineal skin. If the approximating sutures have been placed with intelligence the skin edges will come nicely together, and a few No. 40 cotton stitches complete the repair. The difference to the patient's comfort is immeasurable. The subject is dealt with fully in my article "The Perineum" in the *Clinical Journal* April, 1944.

Our contributor replies. Mr Reddington objects to the principle of making a rectal examination after repairing the perineum. His grounds for this objection are apparently that this examination is unnecessary. But it is all too easy to overlook minor damage to the rectum, and even the steadiest hand may accidentally insert a stitch through the rectal mucosa, especially while repairing an extensive laceration. In the majority of cases probably little harm results. I have in mind, however, a case where a stitch was accidentally inserted through the rectal mucosa, it was discovered but not removed and a recto-vaginal fistula resulted. A rectal examination can do no harm and may save a great deal of future trouble. I agree that, especially in large lacerations, it is sometimes well to insert the topmost stitch in the perineal tissues before completely closing the vagina. Mr Reddington condemns silkworm-gut for uniting the perineal skin. His objections, as given in his article in the *Clinical Journal* are that "it is painful—the ends catch on the pad, it is a path for infection into the perineal tissues, and it is often tied too tightly." The answer to these objections is that if the ends are left long and knotted together they do not catch on the pad and the sutures are not painful. Silkworm-gut is no more a path for infection into the perineal tissues than any other suture material inserted through the perineal skin, in fact, less so than catgut cotton, or linen thread, which are liable to get soaked in the lochial discharge. Finally they should not be tied too tightly, this point was made in the answer to the question.

Shooting Pains in the Head

Dr L GORDON (Leeds) writes In "Any Questions?" of Aug 12 (p 231) there was described a case of shooting pain in the right side of the head following sneezing, straining, or stooping, with negative clinical findings. An interesting case which I saw in 1941 may perhaps throw some light on what may sometimes appear to be a baffling problem. My patient was aged 52, and he gave a history that for upwards of 4 years sneezing, the strain of lifting a heavy weight, or straining at stool caused intense pain behind the eyes extending upwards to the top of the head. The pain made him keep his eyes closed. Latterly, too, he said, he had had stiffness at the nape of the neck during the attacks. When the pain in the head was present it disturbed his balance and made him veer to the left, giving people who watched him the impression that he was drunk. He had some numbness of the left thigh and leg during the attacks. He invariably had to be brought home in a car and put to bed for 24 hours, by which time he had completely recovered, although the attack usually had become somewhat less severe after the first two hours. Clinical examination was entirely negative. The CSF, the optic disks, field of vision, and the ears were normal. The blood and CSF gave a negative Wassermann reaction. I then had the skull x-rayed, and this revealed that he was a well-marked case of Pager's disease with some thickened bone causing pressure on the semicircular canals. X-ray examination of other bones confirmed the diagnosis. No treatment cut short the attacks or gave him much relief until I decided to try him on an inhalation of amyl nitrite on the onset of the attack. This very dramatically relieved his pain and aborted the attack instantaneously.

Vitamin C for All

Dr S HALES (Wembley Park), who is a Fellow of the Royal Horticultural Society, writes in the course of a letter War memorials are in the news and many people are discussing the age-old custom of planting trees. May I suggest that in this matter the medical profession should not stand aside? First, because every

doctor is qualified to give an opinion in matters of botany as well as pharmacology, and secondly, the doctor, when treating his patient, is constantly prescribing vitamins and stressing the importance of including a maximum of fresh fruit in the diet. If we are to win in the near future a widespread planting of trees, may I make a plea that fruit trees be given priority? Why can we not have fruit trees on our main roads and in the roads and public squares of our cities? The official replies will be straightforward, for the Ministry of Agriculture has already declared that roadside fruit trees would become reservoirs for disease-producing pests, which would destroy neighbouring orchards, and the Ministry of Transport considers that children who might be in fear of detection when removing some fruit would run suddenly away and be killed by passing traffic. But may I suggest that it should not be an offence for a child to acquire a surplus of vitamin C from roadside fruit? Public health authorities might produce a poster to remind him of moderation in fruit-eating is in his own interest, and some other poster might remind him that to offer this public fruit for sale would be an offence. Dr W Fox, in a recent issue of the *Journal of the R.H.S.*, suggested that "permanent inspectors of roadside trees appointed by the Ministry of Transport to attend to all matters of tree after-care." Perhaps sanitary inspectors could play some part in the scheme. The expenses of maintaining such a service would balance favourably with that at present devoted to the purchase of vitamin tablets when deficiency has already established itself and that devoted to sickness benefits and to preventable disorders in terms of extra demands on overworked doctors, loss of manpower in factory, or absence from school.

Typewriting in Darkness

One of the base hospitals of the Department of Health for Scotland employs a blind typist in the x-ray department whose work it is to transcribe on the typewriter in total darkness, which she does with facility and accuracy, the remarks of the radiologist. He screens successive patients. This, of course, is a great advantage to the radiologist, who is no longer compelled to rely on his memory or on his own scribbled notes made after each examination. To the blind typist the darkness is no obstacle, and it is suggested that x-ray departments offer such an opening for blind women or men. Every avenue of useful occupation for the blind is to be encouraged though for the sake of accuracy, and as something to be acted upon when a blind assistant is not available, it should be added that a sighted typist who is trained in the modern "touch" method would be able to type with the same accuracy and speed in the darkness. Her disadvantage as compared with the blind typist would be a slower adaptation to conditions when there is no light.

Why Tie the Cord?

Dr J D POLE (Salford, Lancs) writes. The interesting correspondence on this subject reminds me of an experience I had shortly after beginning practice some twenty years ago. A favourite way of protecting the bed was to use sheets of brown paper, and in this case they were fairly stiff, and, unknown to me, overlapped the edge of the bed. I had just delivered the baby with forceps, and was laying it down when, to my horror, the "shelf" gave way and a baby dived under the bed. I was soon after it, and found it yelling lustily. The cord had been twisted off about an inch from the umbilicus and no bleeding. The midwife assisting was so helped with laughter at the whole proceeding that she was unable to give me any help for some time. This cord was never tied, as there seemed no need, and all went well afterwards.

Pin-hole Urinary Meatus

Mr WILLIAM J MOORE, FRF.P.S.G., writes from Glasgow. The causes of pin-hole urinary meatus (Feb 21, p 314) may be congenital or acquired—as, for example, injury to the point of the meatus as the result of circumcision—but whatever the cause there is no doubt that it should be attended to when recognized. When the passage of probes may temporarily enlarge the opening there is a tendency to recurrence. It is suggested, and it has been found successful in several cases, that the enlargement be made electively surgically, the result being that the restoration of calibre is permanent and there is no tendency to recontraction. This treatment also seems to have a beneficial effect on enuresis if it is present.

Priority Demobilization of Doctors

A SERVING OFFICER writes. Of grave concern to many medical officers serving with the Forces over-seas is the length of time they will be detained subsequent to the termination of hostilities. It will be to the advantage of the Admiralty, War Office, and Air Ministry to retain a substantial medical service abroad for some time. Many of us are still paying for our practice and are anxious to return to work as soon as possible. It is to be hoped that a strong representation of the British Medical Association will appeal for priority repatriation of medical practitioners.

LONDON SATURDAY SEPTEMBER 16 1944

LABORATORY TESTS IN THE DIAGNOSIS OF LIVER DISEASE

A REPORT ON THREE PROCEDURES

BY

N. F. MACLAGAN, M.D., M.Sc., M.R.C.P.

Pathologist, E.M.S., Biochemist to Westminster Hospital

(From the E.M.S. Sector Pathological Laboratory, Staines County Hospital, Ashford, Middlesex)

Two important trends in recent work on liver function tests are noticeable at the present time. The first is a broad division between those which test known or accepted functions of the liver and certain empirical procedures which do not test known functions but which are obviously correlated either with certain types of liver damage or with certain diseases in which liver damage is prominent. Among the former the most important are the serum bilirubin estimation, galactose and laevulose tolerance tests, serum protein and urinary urobilin estimations, and the hippuric acid test. The latter include estimation of the serum alkaline phosphatase and choline-esterase activity and the flocculation tests (i.e. the Takata-Ara reaction, the serum colloidal gold reaction, and the cephalin cholesterol test). The flocculation tests are thought to depend upon an increase in the gamma globulin content of the serum, and the hepatic origin of this protein has not been proved. Nevertheless positive results occur principally in diseases in which liver damage is known to be present. The former tests, with certain exceptions, tend to give similar results in all types of liver damage, while some of the latter show striking differences and therefore promise more diagnostic help.

The second trend is the increased sensitivity of most of the tests as compared with those in use 15 years ago. While the earlier complaints of negative results in cases of known hepatic insufficiency have largely disappeared, we are now faced with the opposite finding of a proportion of positive results in a variety of diseases not primarily affecting the liver, such as pneumonia (Carphey and Solomon, 1938), hyperthyroidism (Althausen and Weyer, 1937; Haines, 1939; MacLagan and Rundle, 1940), rheumatoid arthritis (Rawls *et al.*, 1937), following surgical operations (Boyce, 1941), and in scarlet fever, diphtheria, and tuberculous meningitis (Meneghello and Drinberg, 1943). It is hardly surprising that liver function should be impaired in general intoxications of this type, but it complicates the question of interpretation since we need to distinguish between functional impairment and structural damage.

The three procedures described here were originally chosen because they appeared to give the maximum chance of differentiating toxic from obstructive jaundice, but they happen to include one example from each of the three main groups—i.e. a flocculation test, an enzyme test, and a purely functional test. This selection is not intended to preclude the use of other tests such as the serum bilirubin and urinary urobilin estimations which are both of particular value in patients not obviously jaundiced and the first of which is indispensable as a record of the intensity of jaundice when present. The serum protein estimation and the hippuric acid tests also have their special merits, but on the whole their value has been greater in prognosis than in diagnosis (Foley *et al.* 1937; Higgins *et al.* 1944; Quick, 1933, 1939; Boyce, 1941).

I. Serum Colloidal Gold Reaction

Introduced by Gray in 1940 this appears at present to be the best of the flocculation tests from the diagnostic standpoint. It does not test any known function of the liver and should be regarded as an indicator of disturbed liver metabolism rather than a function test. The results reported here were obtained by a modified method described elsewhere (MacLagan, 1944a),

in which 0.05 ml. of serum, 0.5 ml. of special buffer solution at pH 7.8, and 2.5 ml. of gold sol prepared by Patterson's (1931) method are mixed in a single tube. 5 represents complete precipitation of the sol and is the strongest positive, while 0 represents no precipitation and is a negative or normal result. The reaction apparently depends upon an excess of gamma globulin in the serum (Gray and Barron, 1943; Kabat *et al.* 1943), it is thus not directly dependent upon either the total globulin or the albumin-globulin ratio. This was shown by Gray (1940), but also holds for the modified technique used here (Table I).

TABLE I—Serum Proteins (G %) and Gold Reaction in 24 Cases

24	0	3.6	3.2	6.8	Biliary obstruction, recurrent

* Subacute hep. than two months' line between this & findings are very similar in the two

indices of more The dividing line between the two

It will be seen from Table I that, although there is some correlation with the total serum globulin, nearly half the cases with strongly positive gold reactions had normal globulin figures, and one case of recurrent biliary obstruction had a raised globulin and a negative gold reaction. The inversion of the albumin-globulin ratio in nephritis was associated with negative gold tests. These protein estimations were performed by the manometric method of Peters and van Slyke (1932), using the selenate digestion mixture of Beaumont and Dods (1941). The globulins were precipitated with 22.5% sodium sulphate.

Table II gives the serum colloidal gold reactions in 319 cases of liver disease. It will be seen that the test is usually positive in infective hepatitis (93%) and in cirrhosis, and is negative in jaundice due to biliary obstruction (93%). It usually remains negative in obstructive jaundice in spite of increasing liver damage as shown by other tests—e.g. the galactose index—and is therefore of value in distinguishing this condition from the first two. A strongly positive gold reaction (4 or 5-) has not been seen in obstructive jaundice, and is thus of more help in this connection than a negative result, which does not absolutely exclude infective hepatitis. The results in infective hepatitis are usually maximal at the onset of jaundice and

become negative after 3 to 6 weeks, although sometimes persisting much longer. In cirrhosis there is little change from month to month, so that repeated observations help to decide between these two. In arsenical jaundice—i.e., jaundice

TABLE II.—Serum Colloidal Gold Reaction in 319 Cases

	Precipitation Number						Totals	% Pos.
	5	4	3	2	1	0		
Obstructive jaundice	0	0	0	3	0	39	42	7
Infective hepatitis	84	24	22	10	7	11	158	93
Cirrhosis and subacute hepatitis ..	12	0	0	0	0	0	12	100
Arsenical jaundice	5	5	4	6	7	35	62	44
Weil's disease (jaundiced) ..	0	0	3	2	3	11	19	42
Weil's disease (not jaundiced) ..	0	1	1	1	1	10	14	29
Toxic jaundice	0	0	0	1	0	2	3	
Amyloidosis	0	0	0	1	1	5	7	
Liver abscess	0	0	0	0	0	2	2	

occurring during antisyphilitic treatment—and also in Weil's disease negative results are frequent (about 60%) and make the distinction from biliary obstruction more difficult, but fortunately this is rarely a clinical problem. The rather striking difference between the infective and the arsenical cases has been noted elsewhere (MacLagan, 1944b), and suggests a probable aetiological difference in the two groups. In liver abscess and in amyloidosis results have been mainly negative.

As with most other liver function tests some positive results occur in heart failure, in severe chronic anaemia, and in various acute and chronic infections, of which the following are the most important: glandular fever, atypical pneumonia, infective endocarditis, advanced pulmonary tuberculosis, and rheumatoid arthritis (MacLagan, 1944a). In this group the liver involvement was obviously only an incident in the primary disease, but such conditions might complicate obstructive jaundice, when due allowance would have to be made. In practice they can usually be eliminated without difficulty by other means.

Finally, it should perhaps be emphasized that the results given here are not the same as those obtained with Gray's (1940) original technique, which has been adversely criticized by Mateer *et al.* (1942). The technical details referred to above must be followed exactly if comparable results are to be obtained.

II. Serum Alkaline Phosphatase

This estimation, like the gold reaction, does not test any known function of the liver, and raised values are found in infancy and in a variety of bone diseases. In spite of this the test has been much used in jaundice since Roberts's (1933) observation that the level is usually higher in obstructive than in other types of jaundice. The 136 results in Table III were obtained by the method of King and Armstrong (1934).

TABLE III.—Serum Alkaline Phosphatase in 136 Cases

	Range of Values (Normal 3–13 Units)							Totals
	0–13	14–24	25–35	36–45	46–55	56–80		
Obstructive jaundice	0	3	7	13	11	9	43	
Infective hepatitis	6	35	6	0	0	0	47	
Cirrhosis and subacute hepatitis ..	0	6	3	2	2	1	14	
Arsenical jaundice	8	12	2	0	0	0	22	
Toxic jaundice	1	3	0	0	0	0	4	
Amyloid disease	0	0	2	1	0	0	3	
Liver abscess	0	0	2	0	1	0	3	

It will be seen that the test is of some value in distinguishing biliary obstruction on the one hand—usually over 35 units—from infective hepatitis and arsenical jaundice on the other—usually below 25 units and may be within normal limits. However, 15 of these cases fall into the doubtful range (25–35 units), and 3 of the obstructive cases were below 25 units. This is about the same degree of overlap reported by others (Gutman *et al.*, 1940; Giordano *et al.*, 1939; Higgins *et al.*, 1944). If, however, cirrhosis has to be considered the test is of much less value, as figures over 35 are frequent in this condition. In liver abscess and in amyloid disease a raised phosphatase is often present, and may be the only biochemical indication of disturbed liver metabolism.

III. Galactose Index

This index (MacLagan, 1940) is the sum of the four blood-galactose values at 1/2, 1, 1½, and 2 hours after the oral

administration of 40 g. of the sugar. The estimations were performed mainly on capillary blood as previously described, the results being read from the table given below (see Appendix). This table is based on figures given in the reference cited above and does not involve any alteration in the method. The normal limits for the galactose index, based on 50 normal subjects, are 0–160 (0–110 for male medical students). The test is contraindicated by nausea or vomiting from any cause.

TABLE IV.—Galactose Index in 145 Cases

	Range of Values (Normal 0–160)						Total
	0–160	161–200	201–300	301–400	401–500	501–600	
Obstructive jaundice	23	3	7	4	2	0	39
Infective hepatitis	4	5	15	8	3	1	36
Cirrhosis and subacute hepatitis ..	0	1	3	2	2	0	13
Arsenical jaundice	0	1	2	6	1	2	12
Toxic jaundice	0	0	2	1	1	0	4
Hyperthyroidism (from MacLagan and Rundle, 1940)	11	7	16	4	3	0	41

It will be seen from Table IV that the index is nearly always above normal in infective hepatitis, arsenical jaundice, and cirrhosis, but is frequently normal in jaundice due to biliary obstruction. Considerable impairment of function can, however, be demonstrated in certain cases of obstructive jaundice, particularly after the first three weeks, in febrile or cachectic patients, and after repeated attacks of obstruction (MacLagan, 1941). The only normal results in the toxic and infective group were in 4 cases of infective hepatitis in young adults from the Services, a class of patient in which liver function is no doubt above the average. The test is therefore of some value in distinguishing these two groups if interpreted with due regard to clinical data. A normal result in an elderly jaundiced patient is of particular diagnostic value, and has so far been seen only in obstructive jaundice. It is also useful as an extra aid in cases in which the gold and phosphatase tests are equivocal and for assessing the degree of liver damage when present.

The test has also been much used in hyperthyroidism, in which there is impaired tolerance in a high proportion of cases (Althausen *et al.*, 1940; MacLagan and Rundle, 1940; Barnes and King, 1943; and Table IV). Some workers have found it as sensitive as the B.M.R. in diagnosis, although Rundle and I got values decisively above normal in only 75% of our cases; it is agreed that the test is less affected by iodine therapy than is the B.M.R. There is some difference of opinion as to the mechanism involved, since both liver damage and increased intestinal absorption have to be considered. Most recent articles express the view that both factors contribute to the results in hyperthyroidism (Lichtman, 1941; Grauer *et al.*, 1942; Rosenkrantz *et al.*, 1942).

Discussion

It is now generally agreed that a combination of liver function tests yields more information than any one test, and this is particularly true of those described here. Liver function tests are useful in three principal types of case.

1. *Suspected Liver Disease in Non-jaundiced Patients.*—The three tests appear to be sensitive enough to detect cirrhosis, and in common with others they also indicate hepatic involvement in a variety of other diseases such as hyperthyroidism (galactose index), heart failure and various infections (serum colloidal gold reaction), and in liver abscess and amyloidosis (serum alkaline phosphatase). In this group the pigmentary tests—serum bilirubin and urinary urobilin estimations—reach their maximum degree of usefulness and should not be omitted, but they may sometimes be completely negative in cases with known liver damage.

2. *Jaundice of Known Origin.*—The galactose index will reveal liver damage in late biliary obstruction, the other two tests being of no value in this respect. Either the gold reaction or the galactose index may be used to follow the course of a hepatitis, and will often give positive results for some weeks or months after the disappearance of clinical or latent jaundice. In cirrhosis and in subacute hepatitis all three tests have been positive, and the galactose index appeared to have some correlation with clinical severity, so far as could be judged from this small series (13 cases).

3. *Jaundice of Unknown Origin.*—Haemolytic jaundice is usually diagnosed by clinical and haematological methods, and will not be considered here. The way in which these tests can help in the more difficult task of distinguishing obstructive from toxic and

infective jaundice is indicated in Table V, which shows the typical or average results in the types most commonly encountered.

TABLE V.—"Typical" Results with 3 Tests in Jaundiced Patients

	Gold	Phosphatase	Galactose Index
Obstructive	Negative	Over 35	Frequently normal
Infective hepatitis .. .	Positive	Under 25	Raised
Cirrhosis and subacute hepatitis .. .	Positive	Raised	Raised
Arsenical	44% pos.	Under 25	Raised
Weil's disease	42% pos.	?	Raised

The interpretation of the results in these cases must always depend partly upon clinical data, and can never be completely rule of thumb. Nevertheless there are many instances in which a slight acquaintance with the history permits an almost certain diagnosis on the basis of the tests. Considering the gold and phosphatase tests first, three particular combinations appear to have diagnostic significance: (A) A negative gold reaction with phosphatase above 35 units suggests biliary obstruction. (B) A positive gold reaction with phosphatase below 25 suggests parenchymatous hepatic disease and absence of biliary obstruction. (C) A strongly positive gold reaction (4 or 5+) has not been seen in obstructive jaundice and appears to be diagnostic with any phosphatase level. In such cases a phosphatase above 35 suggests cirrhosis rather than acute hepatitis.

It will be evident from Table V that the chances of making the distinction are greater in infective hepatitis and cirrhosis than they are in arsenical jaundice and Weil's disease, but fortunately the two latter conditions do not usually present great diagnostic difficulties. When the gold reaction is positive possible complicating diseases must be considered, but these rarely cause serious trouble in interpretation.

The constancy of these findings is illustrated in Table VI, which includes all jaundiced patients on whom both tests were

TABLE VI.—Combination of Two Tests in 100 Jaundiced Patients

	1	2	3	4	Totals
Gold	Negative	Negative	Positive ⁴	Positive	
Phosphatase	Over 35	Under 35	Over 25	Under 25	
Obstructive jaundice ¹ .. .	22	9	1 (1+)	0	32
Infective hepatitis .. .	0	7	1 (5+)	28	36
Cirrhosis and subacute hepatitis ² .. .	0	7	4 (All 5-)	6	10
Arsenical jaundice .. .	0	6	1 (5+)	12	19
Toxic jaundice ³ .. .	0	2	0	1	3
Totals	22	24	7	47	100

¹ Due to pancreatic carcinoma in 14, gall-stones in 9, hepatic metastases in 6, and other causes in 3. Diagnosis established by necropsy in 15, laparotomy in 15, and by other methods in 2.

² Diagnosis established by necropsy in 5 cases, biopsy in 2, and clinically in 3.

³ Due to T.N.T. in 2 cases and to sulphapyridine in 1.

⁴ Figures in brackets indicate strength of gold reaction.

done. It will be seen that out of these 100 cases 75 fall into group A, B, or C (columns 1, 3, and 4), and in all of these the findings were in keeping with the final diagnosis. The galactose test was confirmatory in 26, omitted in 41, and atypical in 8. The atypical galactose tests were 4 cases of biliary obstruction with secondary liver damage and the 4 cases of infective hepatitis in young adults referred to above.

In the remaining 25 cases (column 2 and one case in column 3) the results did not always give a definite answer, but in some instances the galactose test provided further information. They may be classified as follows: (1) Three cases of obstructive jaundice with negative gold reactions and phosphatases of 16, 25, and 29, and galactose indices of 118, 126, and 114 respectively. In view of the ages of the patients—72, 62, and 40—the normal galactose tests here were felt to be strongly in favour of what proved to be the correct diagnosis. (2) A group of 22 cases with negative or weakly positive gold reactions in which the findings were conflicting and of little diagnostic value. These consist mainly of obstructive and arsenical jaundice, but include some cases of infective hepatitis and toxic jaundice. The galactose test was omitted in 18 of these, and in some it would probably have helped. In two of the obstructive cases a later repetition of the tests showed a rise of the phosphatase to a diagnostic level.

The final assessment of the three tests in these 100 jaundiced patients is therefore that the distinction between biliary obstruc-

tion and generalized liver disease could be made in at least 78, which include about the same proportion of the obstructive and of the non-obstructive cases. It is not, of course, suggested that these rules of interpretation will be infallible, but since no exception to them has been observed in this series they appear to be reliable enough to form a useful diagnostic guide.

As a matter of practical convenience it is easier to do the gold and phosphatase tests first, and to reserve the galactose for cases in which the first two are atypical or in which the degree of liver damage is of interest. The galactose index has, however, a special place in the investigation of hyperthyroidism.

Summary

The clinical value of laboratory tests in the diagnosis of liver disease has been reviewed with special reference to the serum colloidal gold reaction (319 cases), the serum alkaline phosphatase (136 cases), and the galactose index (145 cases).

The first two tests, taken together, often give valuable diagnostic information when considered in conjunction with clinical data. A jaundiced patient with a negative gold reaction and a phosphatase above 35 King-Armstrong units probably has biliary obstruction; one with a positive gold reaction and a phosphatase below 25 units probably has not. A 4 or 5+ gold reaction is against biliary obstruction whatever the phosphatase level.

The galactose index is useful as a confirmatory test in special cases and for assessing the degree of liver damage when present. It is also of value in the diagnosis of hyperthyroidism.

The results given indicate that out of 100 jaundiced patients the distinction between biliary obstruction and generalized liver-disease could be made in 75 cases with the gold and phosphatase tests, and in a still higher proportion if the galactose index was included.

I am much indebted to the medical staff of the Staines County Hospital and of Sector 7 for permission to investigate their patients, and to Prof. A. D. Gardner, Dr. E. N. Allott, Dr. A. J. Amor, Major J. Marshall, and the Middlesex County Medical Society for various sera.

ROYAL COLLEGE OF SURGEONS REPRESENTATION ON THE COUNCIL

The letter by the President of the Royal College of Surgeons of England printed below is being sent to bodies representing the following branches of practice: ophthalmology, otolaryngology, radiology, anaesthetics, and general practice—except such as already have representation on the Council of the College by election under the ordinary procedure.

Dear Mr. President,

The Council of the Royal College of Surgeons regard it as increasingly important to ensure the representation on the Council of branches of practice which at any time have not secured representation by the ordinary process of election. The Council therefore intend to apply for such alterations in the Charters as will enable them to co-opt additional members for this purpose.

The Council wish to make it clear that the College was founded "to promote the science and art of surgery," and it is to assist in this work that the representation on the Council of appropriate branches of practice is thought desirable. The College is not constituted to deal effectively with social and ethical questions affecting not only Fellows and Members of the College but all members of the medical profession. Such questions pertain to some central authority such as the General Medical Council, or some voluntary intraprofessional organization such as the British Medical Association.

It is intended to propose that co-opted members may be Fellows or Members of the College of the same seniority as that required for those seeking election into the Council; that co-opted members of the Council be appointed annually (after consultation with the bodies representing appropriate branches of practice); that the same individual be not eligible for re-appointment beyond five years; and that co-opted members do not have the right of voting for the election to the office of President or Vice-President.

These proposals require alterations in the Charters of the College, and application for such alterations will not be accepted until after the war. The Council, however, consider it desirable that they should have, at an early date, the assistance in their deliberations of representatives of those branches of practice not represented by any of the elected members. They have therefore decided forthwith to invite representatives of appropriate branches of practice to attend the meetings of the Council. The Council have not the power to grant voting rights to those invited to attend the meetings of the Council, but these representatives would have every opportunity to express their views.

I shall be grateful if the will suggest names of a few who are eligible as Fellows or Members from whom the Council of the College could select the one who seems to them most suitable.

Yours sincerely,

ALFRED WEBB-JOHNSON,

President, Royal College of Surgeons of England

The bodies invited to suggest names are the Council of British Ophthalmologists, the Association of Oto-Laryngology, the Faculty of Radiologists, the Association of Anaesthetists, and, for general practice, the British Medical Association.

FIRES AND EXPLOSIONS IN OPERATING THEATRES AND ANAESTHETIC ROOMS

A circular has been addressed by the Ministry of Health to all voluntary hospitals and hospital authorities, and to county district councils exercising delegated powers as to nursing homes, on the subject of fires and explosions in operating theatres and anaesthetic rooms. With it is sent out a warning notice based on recommendations by the Operating Theatre Electrical Committee of the Institution of Electrical Engineers. The placard is for display in each anaesthetic room or operating theatre so that its contents may be brought to the attention of all anaesthetists, operating surgeons, and members of theatre staffs. The notice runs as follows:

WARNING NOTICE

Accidents due to the ignition and explosion of anaesthetic vapours have been attended by serious consequences. Such accidents are

usually due to: (a) the ignition of the vapour by cautery, surgical diathermy, electrical switches, or similar appliances; or (b) the overheating, short-circuiting, or breakage of the small electric bulbs, or their conducting wires or leads, used in various forms of endoscope; or (c) the generation of static electricity, resulting in trolleys, tables, blankets, and even the clothing of operating personnel becoming charged with electricity. Contact with an object at a different electrical potential may cause a spark of sufficient energy to ignite an anaesthetic vapour.

Spirit Lotions, etc.—It should be remembered that the use of spirit, spirit lotions, and other similar solutions which are frequently employed for cleansing the patient's skin, etc., involves dangers similar to those mentioned above.

Precautions and Recommendations

1. Hot-wire cauteries and surgical diathermy present obvious possibilities of ignition, especially near the patient's face. There is also some degree of danger attending the use of x-ray apparatus, motor-driven suction apparatus, and from the general electrical equipment for lighting, heating, sterilizing, etc., unless it is kept away from the neighbourhood of the patient.

2. Five minutes at least before any form of cautery or diathermy is to be used all ignitable anaesthetics—e.g., ether, ethylene, ethyl chloride, cyclopropane—must be removed from the apparatus and a safe agent substituted. A simple and wise precaution is to blow air or some safe gas through the anaesthetic apparatus before use when diathermy is projected, even if this is to be performed under a non-ignitable anaesthetic. It is not sufficient to turn off the "ether tap," as this may not be gas-tight. The ether bottle should be removed, and if it must be replaced, it should first be rinsed out so as to remove any trace of ether.

3. The presence of oxygen and/or nitrous oxide, although these gases themselves are not ignitable, increases the risk of the ignition of other gases.

4. Surgical lamps are often used with some form of regulating resistor. These small lamps are usually made for either 2.5 or 3.5 volts, and it may be dangerous to increase the voltage beyond this even if by so doing the surgeon's request for more light can be met.

5. All the insulated flexible wire connected with surgical lamps should be frequently inspected and renewed. If this precaution is neglected, the insulation may become faulty or some of the constituent wire strands broken, although the lamp still apparently functions normally. Expert technical advice should be obtained on methods whereby the current and voltage of the lamp can be limited to values which greatly reduce the risk of ignition even if a short circuit occurs.

6. Foot switches should be flameproof.

7. Insulated apparatus such as rubber-tired trolleys can be electrified in various ways, as, for instance, by drawing a dry blanket or towel across them. All anaesthetic, operating, and theatre instrument tables, and all trolleys if they are insulated by non-conducting rubber tyres or pads, must, therefore, be fitted with trailing chains which make good contact with the floor.

8. This method is adequate with ordinary granolithic theatre floorings, but is useless when the floor is covered with dry non-conducting rubber, cork carpet, or linoleum.

9. Anaesthetists and others should bear in mind that under suitable conditions they themselves may by their own movements become charged, and shoes incorporating "conducting" rubber may be used as a safeguard on conducting floors. The general use of special "conducting" rubber for tubing and tyres would tend to prevent accidents when it is available. Under war conditions damping of the floor may have to be adopted instead.

10. The generation of static charges is greatly facilitated by a dry atmosphere. Thus the danger is liable to be greater in times of high barometric pressure.

11. Some security may be obtained by slightly damping facepieces, bags, tubing, floors, etc.

12. Should it be necessary during anaesthesia to make or unmake metallic unions or carry out similar alterations to the apparatus, all ignitable gases must be cut off until the alterations have been completed.

General.—The dangers of open flames, matches, cigarettes, etc., need hardly be emphasized. Complete exclusion of all such sources of ignition from the anaesthetic and operating rooms should be strictly enforced.

Brig.-Gen. Leon A. Fox, director of the U.S. Typhus Commission, recently announced plans for the free distribution of typhus vaccine in countries of the Middle East. More than 1,973,000 c.c.m. of vaccine have been supplied to Middle East Governments through Lend-Lease since early in 1943. The Typhus Commission has instructions to make the vaccine available to public health authorities wherever typhus epidemics appear. Shipments of the vaccine have gone to Egypt, Iran, Iraq, Cyprus, Cyrenaica, Eritrea, Palestine, Trans-Jordan, Tripolitania, Saudi Arabia, and Aden. The vaccine has been used for both military and civilian measures of control.

Reports of Societies

STILBOESTROL FOR ADVANCED BREAST CANCER A COMBINED INVESTIGATION

The treatment by stilboestrol of about 100 advanced cases of carcinoma of the breast was reported on by about a dozen speakers at a meeting of the Section of Radiology, Royal Society of Medicine, on June 16.

Dr. FRANK ELLIS (London) said that correspondents in the *British Medical Journal* had drawn attention to the value of stilboestrol in this condition, and a few radiotherapists thereupon decided to treat a number of such cases and present their results. Patients with advanced breast carcinoma often came for radiotherapy, and if some more effective treatment could be found it was important to know of it. It had been possible to assemble only preliminary reports owing to the shortness of the period of observation. He himself described 31 cases in all of which, save one, the effects of stilboestrol could be noted without any complicating effects of radiation. Some of the cases were too advanced for radiotherapy, others were on the waiting list for it, and others again had passed the stage at which further irradiation could usefully be given. The doses of stilboestrol he had employed were relatively large unless the patients were very intolerant; the average was 15 mg. a day. In some cases—though in none of those which showed improvement under treatment—the administration was followed by nausea and vomiting; other manifestations were activity of the breasts, with pigmentation, tenderness of the areola, and in some cases resumption of menstruation. Eight patients had shown improvement; their average age was 67.6 years. Fifteen, the average age being 53.5, became worse under treatment. Two patients became worse during the administration, but improved, both subjectively and objectively, after it stopped. His conclusions were that stilboestrol might make the malignant condition in a younger woman worse, but it might have value in the older woman. It did not bring about any improvement in bone metastasis of breast cancer.

Dr. S. B. ADAMS (Bristol) said that of 10 cases treated, 4 showed improvement, 1 being a woman aged 82. In 3 cases some of the lesions were observed to grow in size during treatment, though the main lesion shrank. The first case began treatment in July of last year; only 1 mg. of stilboestrol was given daily. Improvement took place to a marked degree. The primary in this case was a deep cancer crater of the breast, with diffuse infiltration of the chest wall and skin involvement, and this had healed leaving a fibrous scar with two small residual nodules. The liver had increased in size since treatment started, though whether this was due to secondary deposits could not yet be stated.

Dr. G. W. BLOMFIELD (Sheffield) said that his cases did not show any appreciable toxic symptoms, though some were disturbed by psychological effects when menstruation restarted years after the menopause. Of the 10 cases treated, 8 derived no benefit so far as could be estimated, and in 2 the result was indeterminate. In 6 of the cases the growth was such that it could be accurately measured and any improvement could be assessed.

Dr. ALEXANDER HADDOW (London) gave details of 13 cases, several of which had previously been treated by surgery and had shown recurrence, or by high-voltage x rays, though after a sufficient interval not to affect the results produced later by stilboestrol. The stilboestrol was given in total doses varying from 75 mg. to 676 mg. over periods of from 4 to 24 weeks. Administration was by mouth or by intramuscular injection, in some cases by both routes. In the cases responding in some degree lesions previously red tended to show a purplish tinge, or sometimes pallor; small skin nodules were flattened and occasionally disappeared; larger nodules and masses might undergo partial regression. In these 13 cases there was continued advance of the disease in 9, a temporary improvement in 3, and a marked and more lasting benefit in 1. This last, a woman of 64, had continued to show improvement over a period of 4 months. Favourable responses were much more likely in the older and post-menstrual group.

Dr. W. M. LEVITT (London) described 11 cases, all advanced but all well enough in their general condition to be treated as out-patients. Only one showed any marked improvement. In this case, a woman of 69, the ulcer shrank in four weeks from 11×6 cm. to 4×5 cm. He thought it would become more and more evident that with increasing age there is improvement in response to treatment.

Dr. R. McWHIRTER (Edinburgh) had 37 cases, of which were under the age of 58. Of these, 2 improved and 18 did not improve. Of 17 cases over the age of 58 there was improvement in 3 and no benefit in 14. One of the improvements was spectacular. It included the healing of the ulcer and almost complete disappearance of the disease. This case was one of poorly differentiated scirrhus of the breast, and the woman's age was 75.

Dr. EDITH PATERSON (Manchester) described 13 cases treated with stilboestrol and 23 with triphenylchloro-ethylene. In 11 stilboestrol cases, the average length of treatment was 12 weeks, the average daily dose 5.8 mg. The growth regressed in 2 cases, it was stationary in 8, and it progressed in 3. The average length of treatment in the 23 cases given triphenylchloro-ethylene was 27 weeks, the average daily dose 3 g. There was regression in 9 cases, the condition was stationary in 4 and progressive in 10. The most striking regressions were in the older patients.

Mr. C. J. L. THURGAR (Newcastle) had treated 10 cases, with promising results in 2 and a spectacular result in 1. Of his 4 cases under the age of 58 not one improved. The spectacular result was in a patient aged 58 who had had 10 weeks' treatment. This patient had multiple glands and skin nodules after a radical operation, and all the deposits had disappeared. The treatment was begun in April last.

Dr. J. Z. WALKER (Scunthorpe) also described 10 cases. In 3 the treatment had considerable palliative value; in 4 it failed; in 2 it was discontinued owing to intolerance; and 1 patient died during the period of treatment. One of the failures was a case of male breast cancer; the disease advanced rapidly under treatment, and the patient died within a month.

Prof. B. W. WINDEYER (London) gave particulars of a further 10 cases, 2 of which had had no previous treatment, 5 had had surgical removal, and 7 x-ray therapy. The average period of observation was 5 months. In none had there been complete disappearance of the growth, but at least 3 had improved, the ages being 43, 54, and 55.

Summary of Results

In the whole series recorded by the various speakers there were 69 patients under the age of 58, of whom 43 had not improved, and none showed spectacular improvement. Of the 52 patients over 58, at least 17 had improved, and 6 or 7 were reported as showing spectacular improvement amounting in some cases to complete disappearance of fairly advanced disease.

Prof. E. C. DODDS said that, particularly in patients over 58, it was most important to determine the general systemic effect of an oestrogen, because anyone with experience of treatment of disorders of the menopause with synthetic oestrogen would know the great physical and psychological effects, and these were likely to influence the general condition of the patient with carcinoma. He had been surprised at the smallness of the dosage reported by some of those who had taken part in the investigation; it seemed to him that it would have been worth while to give really massive doses. He was also surprised that synthetic oestrogens, which were more powerful than stilboestrol when given by mouth, had not been tried. If the work was continued a control series of cases treated with lactose tablets should be taken.

Dr. LEVITT said that what had been presented was regarded only as a preliminary experiment to obtain an idea whether the investigation was worth pursuing. He proposed (and it was agreed) that a committee be formed consisting of those who had reported on that occasion, together with Prof. Dodds, and with Dr. Alexander Haddow as chairman, to follow the matter up further.

Dr. N. S. FINZI, from the chair, said that radiologists had a large number of cases of malignant disease of the breast, but he wondered how many of them had seen spontaneous

appearance of a carcinoma. In his long experience he could recall only one case of his own, and one other which he saw at the R.S.M., and even in his own case there was either recurrence or a new tumour in the other breast later on. The improvements reported might be only temporary. The only male case that had been mentioned did very badly; possibly a male patient the male hormone ought to be given.

Correspondence

Infective Hepatitis

SIR.—Prof. Witts's interesting summary of infective hepatitis (June 3) prompts me to record some observations, made by Capt. Damodaran, R.A.M.C., and myself, on 450 cases admitted to the medical division in a general hospital in Malta in 1941–3.

Siege conditions favoured the epidemiological aspects of the study, the civil population and military personnel remaining more or less static till 1943. Thus the fallacy mentioned by Prof. Witts was enormously reduced since it could be assumed, for this period, that the experience of the garrison was uniform.

Infectious hepatitis exists in a mild sporadic form as "catarrhal jaundice" affecting children and young adults of the native Maltese, its highest incidence being in late autumn and winter. Cases have occurred among the British garrison, and since 1932 there has been a steady increase from 4.38 per 1,000 to 20 per 1,000 in 1939. There was a further increase in 1940 and in 1941, and in 1942 it reached almost epidemic proportions, the monthly incidence curve showing almost perfect symmetry with a maximum for the months of October, November, and December, and a minimum in April, May, and June.

Among the 450 cases 86% were between the ages of 20 and 29. The incidence as between British and locally enlisted troops was as 10:1. The one fatal case of acute cytolytic necrosis of the liver was in a Maltese. There is, from the careful study of the living conditions and contacts of known cases, abundant evidence confirming the well-accepted views of the approximately 30-day incubation period, the short pre-icteric infective phase, and the probability of droplet infection by "speech contact." Infection conveyed by direct transfer of the infective agent through contaminated syringes and needles can be eliminated in all but the group of post-arsenical hepatitis, of which 13 occur in this series. An investigation of the prothrombin content of the blood (Quick's method modified by Kark and Souter) during, and one month after, the attack of jaundice showed a variable lowering of the percentage figure. It never was it below 30%, and in all except two it was or above 95% in one month. The clinical types encountered were:

(1) *Gastro-intestinal type* (53%). Insidious onset; anorexia, often fully and unexplained, followed by nausea and vomiting; fever less than 100°, with dark urine and clinical jaundice in 3 to 5 days.

(2) *Febrile type* (30%). More sudden, even abrupt onset with temperature ranging from 101 to 103°, often simulating sand-fly fever (malaria was not present in Malta), followed by nausea, anorexia, and abdominal discomfort—sometimes vomiting, and ending in 2 to 4 days from onset.

(3) *Ambulatory icteric type* (10%). Cases with no notable general symptoms or, at most, slight malaise, usually insufficient to cause a soldier to report sick. He is observed to be yellow by his colleagues while still on duty.

(4) *Hepatitis without icterus* (7%). The prodromal symptoms are similar to the gastro-intestinal or febrile type with fullness and gastric discomfort and at least two fingerbreadths enlargement of the liver. No clinical jaundice develops, but latent jaundice is shown by a raised icterus index of 10 to 14 and/or the passage of a slightly bile-stained specimen of urine. Small groups of cases were followed with several members showing the typical gastro-intestinal febrile clinical picture and jaundice, and a single member with typical symptoms of onset, enlarged liver, yet not having jaundice. Was thus that attention was drawn to hepatitis without icterus.

The last two groups (3 and 4) are of special importance in epidemiological studies, for, being "subclinical" types, they are presumably infective at some stage. True relapse is rare when it occurs it is apt to be severe. A single attack does

not necessarily confer immunity. One of my general duty officers in Malta had a typical attack of "catarrhal jaundice" when he was my house-physician in Leeds in 1937. He again fell a victim to infective hepatitis in 1942 when working in the medical division in Malta.

Among many other interesting facts a note may be added on the adverse effects of other hepatotoxins, particularly alcohol (acting in the presence of an epidemic) upon an individual who is incubating the disease, in provoking an overt attack, or in worsening and prolonging an attack otherwise mild, and in causing a "relapse" or second delayed attack of jaundice. We have detailed studies of at least 12 cases of relapse of jaundice after the first attack of infective hepatitis due to alcohol—not necessarily excessive—taken from 12 to 72 hours previously. This period of sensitivity of the liver may last at least 6 months, during which time alcohol is potentially dangerous. One patient was able to determine exactly how much alcohol could "turn him yellow." He said his "hangover" was out of all proportion to the amount consumed, and, after several unhappy experiments with progressively smaller quantities of liquor producing this untoward effect, he became a total abstainer. Some other effects of alcohol in the presence of infective hepatitis are epitomized in the following history:

A squadron of R.A.F. was moved from one landing ground to another in the Middle East in the last week of November, 1942. A section of the personnel lived and messed together and were closely mingled; one of their number at this time had a raised temperature for a few days and was removed to hospital, where he later developed jaundice. In the meantime the squadron moved to Malta (Dec.). On Christmas and Boxing Day a substantial quantity of drink was taken by most of the section. In 24 to 48 hours eight of their number developed jaundice. Two abstainers, however, living companions of the affected personnel, also developed jaundice, but it was mild in character and delayed a further seven days—"I am, etc.,

STANLEY J. HARTFALL, M.D., F.R.C.P.,
Lieut.-Col. R.A.M.C.

Treatment of Haemorrhage and Shock

SIR.—In the early days of the Spanish Civil War, and, indeed, right through it, the results from the transfusion of blood for the treatment of haemorrhage and shock among battle casualties were most contradictory and certainly not as satisfactory as those obtained with the improved methods in current use.

While many surgeons advocated its use and assured us that their results were excellent, others, like myself, soon gave up transfusing in the certainty that its theoretical advantages were outweighed by its practical disadvantages. This might have been due to the fact that we administered the blood too rapidly, giving too much in too short a space of time. By making frequent B.P. readings I discovered that shortly after transfusion there was an initial rise in B.P., but this was invariably followed by a dangerous fall which often coincided with the commencement of an operation, thus adding to its dangers. I don't know how the Group IV blood, with which we were amply supplied, was prepared, and since those days an improvement may have taken place which, in conjunction with the present-day slow-drip method, may be the reason for the well-earned popularity of blood transfusion in this war.

I treated over 5,000 wounded of the type which must receive urgent surgical treatment close to the firing line, and I therefore had considerable material upon which to study the clinical aspects of shock and haemorrhage. This led me to devise a method for raising and maintaining B.P. which served me well throughout the war and which I believe to be quite as good as any other, particularly in cases of shock, though I also used it in cases of haemorrhage accompanied by shock, a type of case very common in war wounds.

I administered, by intravenous drip, a mixture of calcium gluconate, hypertonic saline, and pholedrine (veritol), which I finally decided upon after trying out other drugs such as adrenaline. Veritol contains gr. 1/3 of pholedrine per c.cm., and, although much greater doses can be administered, we found that three ampoules (gr. 1) a day, added to the calcium and saline, were sufficient even in the gravest of cases. Our aim was to obtain a systolic B.P. of 130, and we regulated our drip to this end. Cases differed considerably in their response according to the degree of shock and haemorrhage, and hence the total amount of fluid, glucose, and pholedrine administered

varied accordingly; but we never gave more than three ampoules in 24 hours, not more than three litres of glucose saline, which was usually hypertonic for the first litre but diluted gradually and slowed up as the general condition improved, while the amount of calcium gluconate we kept constant for all cases at 2.5 g. daily—three 10-cm. ampoules of the 8% solution.

A typical example of the results obtained is afforded by the following case of a young sub-lieutenant aged 17. Multiple wounds from mortar explosion, left arm shattered near the shoulder, left leg with gaping wound, and fractured femur at the upper third. When he was taken off the ambulance all bleeding had stopped, he was completely unconscious, and was put aside to be examined by me before being sent to the mortuary. On auscultation an occasional very faint heart-beat could be appreciated. A vein was dissected out in his sound leg and the calcium-veritol-saline drip at 120 drops per minute started. Within a few minutes he had recovered consciousness and his wounds had to be packed and bound tightly to stop bleeding. Within two hours his systolic B.P. was high enough to warrant a disarticulation of the shoulder-joint and debridement and application of closed plaster to his leg. He received a total of 6 ampoules of pholedrine in 48 hours, after which it was discontinued. He was evacuated to a base hospital eight days later, after removal of stitches and change of plaster.

The present phase of the war is going to make great demands on the blood banks, and blood may not be available at all times in all places. The calcium-glucose-pholedrine mixture can be used successfully in place of blood and plasma. It is with this object in view that I have ventured to encroach upon your valuable space.—I am, etc.,

E. MARTINEZ ALONSO, M.B., Ch.B.

Queen Mary's Hospital, Roehampton, S.W.15.

Experimental Shock

SIR,—Prof. Moon's detailed analysis of shock (June 10, p. 773) is timely and valuable, but there is one point on which I should like to comment. His experimental evidence has been obtained largely by the method of implanting minced muscle in the peritoneal cavity of dogs. This method was used by me in rats with similar results, the animals dying on an average 12 hours after operation with obvious clinical signs of circulatory deficiency, such as cyanosis and coldness of the skin, and a haemoconcentration of 40%. But a bacterial peritonitis was found in every case despite careful measures of asepsis the preparation and implantation of the muscle. The minced muscle provides an ideal culture medium for organisms, and a single sporing bacillus will produce an army within a few hours. The admixture of a little proflavine powder prevented the bacterial growth, and the animals did not develop clinical shock or haemoconcentration.

It would seem that the effects of muscle implantation are not due to tissue autolysis, as claimed by Moon, who did not report bacteriological examinations, but to bacterial toxins. Several of the features which he lists as characteristic of secondary shock, such as persistent vomiting and a dilated and atonic gastro-intestinal tract, are features of bacterial peritonitis rather than of traumatic shock. Since bacterial activity probably plays a small role, if any, in the development of secondary shock following extensive trauma or severe burns, it is wrong to apply to this type of shock conclusions which appear to come from the study of an infective process.

The rats which had proflavine powder implanted intraperitoneally, with or without minced muscle, died in 3 or 4 days with gross abdominal distension and ileus, although the peritoneal fluid remained sterile. This suggests that solid proflavine is not suitable for intraperitoneal administration in large doses to human beings.—I am, etc.,

Radcliffe Infirmary, Oxford.

HERBERT HAXTON.

Ether and the Oxford Vaporizer

SIR,—I am grateful for the bit of sugar in the first paragraph of Dr. Durrans's letter (June 17, p. 826), in which he is appalled by the high incidence of vomiting reported in a paper by two members of this department. A figure giving the frequency of post-operative complications depends in considerable part on the diligence with which these are sought and the honesty with which they are recorded. I remember some years ago Dr. Freda B. Bannister embarking on an investigation which entailed radiological examination of the chests of patients who

had been subjected to abdominal operations. After some months of careful work she obtained concrete evidence that what others had conveniently dismissed as "reactionary temperature" was often demonstrable on an x-ray plate. She was then greeted in some quarters with: "I hear you are getting more 'chests' than you used to!"

Recent correspondence in another journal suggests that it is profitless, in fact misleading, to compare statistics from different sources. Some strain at, and record, gnats, while others digest camels without deeming the incident worthy of note. I recall two relevant facts. (1) At a meeting—well attended by surgeons—an anaesthetist provided figures to show that vomiting rarely occurred in his patients. A subsequent private cross-examination elicited that he disregarded vomiting on the day of operation! (2) A patient was subjected to appendicectomy under nitrous oxide. True, the patient didn't vomit, but for 24 hours afterwards was grey, nauseated, and ill at ease. The anaesthetist recorded this case as "vomiting—nil." A bout of vomiting would have spoiled his figures, but would have resulted in a happier, healthier patient.

There is often a great discrepancy between the bouts of vomiting recorded by an observer and those remembered by the patient. Mushin and Wood wished to eliminate as many variables as possible, and preferred the evidence of observers instead of relying on the memory of the patient, notoriously unreliable in the immediate post-operative period, because of the combined effects of hyoscine, morphine, anaesthetic, and operation. Lastly, the Oxford vaporizer was introduced not as a panacea for post-operative vomiting, but as a means of providing simple safe anaesthesia, particularly in war conditions. I have just returned from a hospital where one anaesthetist was responsible for four operating tables (one for induction) throughout a busy day with the help of three orderlies using Oxford vaporizers. Three surgeons, working simultaneously, were kept supplied with a stream of patients, and 38 operations were performed in 10 hours without incident.—I am, etc.,

Nuffield Department of Anaesthetics, Oxford.

R. R. MACINTOSH.

SIR,—Dr. Durrans's letter under this heading (June 17, p. 826) reads so strangely that it is worthy of passing comment. He refers to the series of cases in the experiment carried out by Drs. Mushin and Wood as "admittedly" uncomplicated, and emphasizes the "admitted" incidence of post-operative vomiting.

The authors of the experiment did not claim that the administration of ether was done under the most favourable conditions, though their use of the vaporizer might well imply this. I imagine that the use of the vaporizer would at least allow them to keep one factor in the experiment constant, and but for the No. 2 vaporizer I know of no other apparatus likely to do so. He then reveals the truth that the ether vaporizer delivers ether! Does he try to infer that this was not "admitted" in the experiment? Does he seek to disprove the statement made by the Nuffield Department of Anaesthetics that "the concentration of ether vapour in the inspired mixture is indicated by the position of the tap"? I believe that one can have the vaporizer calibrated to deliver a known concentration of trilethyl or chloroform.

Dr. Durrans regrets that the Oxford vaporizer was not designed twenty years ago, and strongly deprecates submitting the patient to the discomforts and dangers attendant upon ether. Less than five years ago (*B.M.J.*, Dec. 2, 1939) Macintosh and Pratt wrote of ether: "This drug, discovered almost a hundred years ago, has never lost its pride of place as the safest and most reliable of anaesthetics." I am unaware of any ridiculous claims put forward for the clinical performance of the apparatus. I have used it since first it became available and with gratifying results.—I am, etc.,

Salisbury.

A. D. H. SWINSON.

Post-operative Vomiting

SIR,—Dr. Barbara Crawford (June 17, p. 826) states that the oral administration of adrenaline is of value in controlling post-operative vomiting. The publication of this letter was stimulated by the paper by Dr. Wood and myself on the effect of nicotinic acid on post-operative vomiting. The type of clinical research exemplified by this paper requires

its performance only painstaking observation, honest recording, and analysis of the results. Dr. Crawford would be performing this service if she would submit her suggested treatment to this *etc.* or, alternatively, publish the evidence on which her statement is based. Anaesthetists would thereby be indebted to her not only for suggesting what may be a valuable remedy but for being spared the necessity of carrying out an investigation to confirm what may be only a clinical impression.—I am, *etc.*,
Nuffield Department of Anaesthetics, Oxford WILLIAM W. MUSHIN.

Administration of Pentothal

SIR.—I am deeply grateful to Dr. F. W. Roberts and to Dr. H. B. C. Sandiford (June 17, p. 825) for their clear and timely warning of the dangers of overdosage of pentothal in deeply shocked cases. I, however, plead not guilty of having underestimated these dangers. The administration of any anaesthetic agent to a seriously shocked patient is a highly delicate procedure, calling for a considerable degree of experience and skill. Accordingly, those surgical units whose duty is to assist the recently wounded—where shock is common and severe—are staffed by specialist and graded anaesthetists. Nothing less would be good enough for our fighting men.

Our ranks at home have, however, been depleted, and we have to find a simple formula to encourage the "occasional" anaesthetist to tackle with confidence the average uncomplicated case. If we have to achieve this purpose it is necessary that the instructions given should be simplicity itself and should allow for a reasonable margin of safety. As Dr. Sandiford agrees with me, within these very strict limitations, may I consider his most valuable comments and instructions to be complementary, not contradictory, to mine?—I am, *etc.*,

E. MONTUSCHI,
E.M.S., Sector X

Episiotomy

SIR.—I feel that Dr. Neilson Dow's memorandum (June 17, p. 813) should not be allowed to pass without comment. The author seems to overlook the fact that it is essential, when repairing an episiotomy, to unite the deeper layers—that is, the muscles—of the perineum, and, when necessary, the levator ani. If this is not done, a deficient perineum is certain to result with considerable disability and the risk of development of rectocele. Surely, if the method outlined is adopted, the result must be that only the mucous membrane of the vagina and the skin of the perineum are united, unless further sutures are inserted. Thus the method, if it is to be an effective means of repairing an episiotomy, defeats its own end, which is, in Dr. Neilson Dow's own words, to make it so that "there is no need to give chloroform after birth to relieve the pain of stitching up."

I am glad to have an opportunity of protesting against the prevalent and pernicious practice of giving a general anaesthetic for repairing the perineum. This is extremely dangerous, as it is well known that a parturient woman tolerates a general anaesthetic very poorly, and alarming or even fatal collapse may occur. Such anaesthetics are often given by a doctor working single-handed and having to rely on the midwife to maintain the patient in a state of unconsciousness. The danger of chloroform in the pregnant and parturient woman has been emphasized by Sheehan (*J. Obstet. Gynaec. Brit. Emp.*, 1941, 47, 49), but no general anaesthetic is entirely safe in the period immediately following childbirth.

The perineum can be repaired painlessly, thoroughly, and with complete safety, using local infiltration with procaine. This procedure was fully described by Prof. Browne in 1928 (*Lancet*, 1928, I, 1281), and it has been and is in routine use in the obstetric unit at University College Hospital. Local analgesia has now been used for perineal repair in many thousands of cases without a single fatality. It has the further advantage, besides complete safety, that it can be used by a single-handed practitioner without the additional anxiety of caring for an unconscious patient while his attention is, or should be, fully engaged in repairing the damaged tissues.

Finally, I cannot agree with Dr. Neilson Dow that episiotomy is only "rather rarely indicated." On the contrary, I should say that it is one of the most useful procedures in obstetrics. It is indicated in labour when a tear of the perineum is seen

to be inevitable, in almost all cases of forceps delivery in primigravidae, and in every case of breech delivery in a primigravida, unless the baby is small. An episiotomy is a cleanly incised wound, and is thus much easier to repair than a spontaneous and possibly ragged laceration. Timely episiotomy will often prevent severe damage to the tissues of the perineum and vagina and even of the rectum.—I am, *etc.*,

JOSEPHINE BARNES,
University College Hospital, London First Assistant, Obstetric Unit.

Mastoiditis and Mastoidectomy

SIR.—I have read with considerable misgiving Dr. H. Hilton Brown's correspondence (March 18 and May 6) on this subject. One gathers from his observations that he is in complete agreement with what is, as he states, the public viewpoint on mastoid operations. The public is represented as regarding the mastoid operation as of a very serious nature, often fatal, with frequent great disfigurement, possible facial paralysis, possible deafness, a continuation and aggravation of the ear discharge, and very painful and prolonged post-operative dressings. In short he would have us believe that the mastoid operation for acute mastoiditis is very dangerous, and that it is quite unnecessary. I find it impossible to agree with these assumptions.

During recent months I have performed 97 conservative mastoid operations for acute mastoiditis. Fourteen of these had serious complications before operation, and it is instructive to consider these cases in some detail.

(1) A case of general streptococcal meningitis. (2) A case of meningeal reaction with a turbid sterile C.S.F. (3) A case of otitic hydrocephalus in deep coma, associated with a large extradural abscess in the middle cranial fossa. (4) Five cases of pennisinus abscess, one of which was associated with lateral sinus thrombosis. In another case the inflammatory infection in the middle ear had resolved with a tympanic membrane somewhat thickened and opaque in appearance, but otherwise normal; the presenting sign was a subperiosteal abscess over the mastoid, which at operation was found to be associated with coalescent suppurative mastoiditis and a large pennisinus abscess. (5) A case of suppurative petrositis with Gasserian ganglion neuralgia, external rectus paralytic squint (6th C.N.), transient facial paresis, transient vertigo, middle-ear deafness, and a small extradural abscess in the region of the Gasserian ganglion (Gradenigo's syndrome). (6) A case of abscess formation at the apex of the mastoid process with the pus tracking down the neck deep to the sternomastoid muscle (Bezold's abscess). (7) Two cases of acute mastoiditis associated with focal nephritis. (8) Two cases of haemorrhagic inflammation throughout the mastoid process. The large majority of the remaining 83 cases were of coalescent suppurative type of mastoiditis.

In this series there was only one fatal case—namely, the one of streptococcal meningitis, and this patient was almost moribund before operation. There was no case of facial paralysis, and with the exception of a few of the complicated cases scarring was inconspicuous. There was one case of persistent otorrhoea associated with infection by the *Pneumococcus mucosus* and a case of unhealed perforation—probably of old standing. In the other cases good hearing returned with dry ears and healed ear-drums. This included the case of suppurative petrositis, which is a severe test for functional recovery. In this case it is interesting to note that the squint due to paralysis of the external rectus muscle recovered completely within a few weeks of a conservative mastoid operation and drainage of a small extradural abscess in the neighbourhood of the Gasserian ganglion.

In view of these results Dr. Hilton Brown's suggestions that mastoidectomy is dangerous, *etc.*, do not appear to be well founded. As regards painful and prolonged post-operative dressings, if the mastoid wound be insufflated with sulphonamide powder and closed except for the lower third of the incision—which will provide for drainage—and if the cavity is syringed out occasionally with a few c.c.m. of 10% albidol solution, the wound will heal soundly within a few weeks, with little discomfort.

The degree of conservatism exercised in selecting cases for operation is illustrated by a review of the following cases. In a series of 132 cases of acute mastoiditis treated at one hospital complete resolution occurred in 77 cases with conservative treatment, including sulphonamides; the remaining 55 cases had mastoid operations either immediately or after conservative treatment had failed. Paracentesis of the tympanic membrane

is considered to be a conservative measure. In this connexion it is true to say that sulphonamide treatment has not reduced the number of cases of mastoiditis requiring mastoidectomy that was hoped at one time.

In conclusion it may be claimed with all fairness that the conservative mastoid operation done at the right time is a safe procedure, which preserves life, restores function, and reduces very considerably the incidence of chronic otorrhoea.—I am, etc.,

London, W 1

W. H. B. MAGAURAN, F.R.C.S.

Morning Protamine and Evening Soluble Insulin : A New Abuse

SIR.—Six unfortunate insulin cases have been referred to me lately from different parts of the country in great difficulty, under a novel use of insulin, so unsuccessful and irrational that it deserves condemnation. They have been given P.Z.I. (mostly 20 units) before breakfast and soluble insulin (mostly 20 units) before supper, a treatment which shows surprising ignorance of the different action of the two types of insulin. In this way the weak insulin is given to counteract the day's food, and hence the patient is loaded with sugar after all the day's meals; and the strong insulin is given in the evening with resultant hypoglycaemia about 1 to 2 a.m. There is no space here to expose in detail the inimitable bad results from this abuse, nor do I often use your columns for self-advertisement, but I would ask the doctors involved to study the last edition of *The Diabetic Life*, which demonstrates the 'unphysiological' nature of the above treatment.—I am, etc.,

London, W 1.

R. D. LAWRENCE.

Ketosis in Children

SIR.—In a series of 239 consecutive cases of tuberculous disease of the abdominal lymphatic glands Clark and Colt (*Lancet*, Jan. 16, 1937, p. 125) found that ketosis was present in the great majority of subacute and acute cases when vomiting had been absent or infrequent. This would fit in with Dr. Bray's note (June 17, p. 824) that ketosis occurs after "emotion, exertion, or excitement." The sign is so marked and so constant that it may be relied on in a difficult case to differentiate the condition from acute appendicitis or from partial intestinal obstruction. An x-ray examination is always advisable.—I am, etc.,

G. H. COLT.

Service Medicine

SIR.—I am very much interested in the correspondence in our columns on this subject. After 4½ years' experience in the administration of hospitals at home and over-seas I agree that the treatment of the Service patients is excellent, better perhaps than that of the patient in the civil hospital. But it must be remembered that for the most part this treatment is, during wartime, carried out by specialists who have not only been trained but have been brought up in teaching or good non-teaching hospitals with all the traditions which this means. These officers, moreover, at first welcomed the change in their daily routine—the greater leisure they had in which to think and the opportunities for communal discussion which they enjoyed—but later, at least in my experience, they hankered after their old way of life and lost their enthusiasm for the Service community. While there were some excellent regular specialists, in my opinion the "bringing up" of the clinician in Service conditions in peacetime did not produce anything like the same quality of physician or surgeon as that of the voluntary hospital staff; but in fairness it must be admitted that the peacetime Army did not offer any comparable clinical material.

I also agree with one of your correspondents that the majority of the higher-ranking administrative officers were most helpful and quite delightful to work with, but still I feel that the system is wrong. If administration is done by an individual with a clinical bent who wants to study disease in the human body, however interesting he may find administrative tasks, he is always beset by the feeling that this is not his job, and the constant inspections of kitchens, vegetable stores, latrines, and wash-houses, which are very necessary, become inexpressibly tedious. Certainly he can, if he likes, see clinical cases, but

it is rather by the courtesy of his junior officers, and he never can have the close contact and personal responsibility for diagnosis and treatment of the clinician, though theoretically he is responsible for both.

If the administrator is not clinically minded, he may find enough to do without interfering with his clinicians, and no doubt most do, but he is in a position to interfere to a serious extent. He has almost autocratic power in his unit, and may or may not use this well. Without his encouragement and consent clinical meetings and discussions would be difficult to hold. The writing of papers and other communications to the medical press may be discouraged, and their forwarding for publication may be so delayed that their usefulness may have passed or some other worker may have got in first. Directions for treatment of various diseases are given by consultants, which are most useful, but they are meant to be guides. They may, however, be regarded as instructions irrespective of the special circumstances of a case, which may demand quite different treatment. Inquiries may be ordered and results demanded without any consideration of statistical validity or control of findings, and policy may be initiated based on totally erroneous premisses. No doubt all such mistakes will eventually be rectified, but meanwhile there may be much waste of time and effort, and, what is worse, irritation and a sense of futility among the team of clinicians whose potentialities for united work are the great argument in favour of Service medicine. Under the stress of war Service medicine is good, but in the reaction of peace it seems likely that the stimulus of altruistic individualism is likely to give better results.—I am, etc.,

Bath.

R. G. GORDON.

SIR.—Only the professional eminence of Air Cdres. Cade and Conybeare and the possibility that their experience has been of the ivory tower variety prevents me from condemning their letter outright as "apple polishing" (May 20, p. 574). I cannot speak for British Forces, but I think that sentiments of the majority of medical men in the Canadian and U.S. Forces are identical with those of your correspondent of April 1 (p. 470).

Examples of bad staffing are not rare, but here the main complaint is of over-staffing. Dr. Frank Lahey is chief of the Procurement and Assignment Board which furnishes doctors to the U.S. Forces. I suggest that Air Cdres. Cade and Conybeare read his remarks made a few weeks ago at the meeting of the American College of Surgeons, in which he called attention to the waste of medical man-power in the Forces. Your space is too valuable for a detailed list, but I will tell of the complete medical and enlisted staff of a 1,000-bed general hospital shipped to the South Seas where for weeks they had neither patients nor buildings, and the medical officers were engaged in stavedoring, felling trees, and so on.

I know the task of furnishing medical men for the armed Forces is a big one. No one wishes to deprive any soldier of his needs, but I am sure the job could have been done better and that glaring evils go uncorrected.—I am, etc.,

Prairie Grove, Arkansas

FRANK RIGGALL.

SIR.—I have just been reading a letter published in your issue of April 1 and entitled "Service Medicine?" It was received in our mess with feelings of disgust—both for the authors and for the journal which published such gross libel. I may add that more than 50% of the members of the mess are M.Os.

I myself have been in the Army for two years, and admit that I entered it with a poor opinion of both the Army and its medical service. During this past two years I have seen the Army from many different aspects while serving with different types of medical unit, both at home and abroad. During that time I have considerably revised my opinions; I now feel proud to be in the Army, and hold in high respect the organization of the R.A.M.C. I freely admit that the R.A.M.C. has its faults, but I maintain that these are considerably fewer than I found in the chaos of civilian medical practice. If I were a layman without much money I would far rather be treated for illness by the Army than as a civilian. I admit that I have met medical officers of high rank whom I have considered incompetent, but I met many, probably more, of

such type in civilian practice. Those met in the Army are only too often either Territorials or civilian consultants who have been given high rank because of professional ability but who are failures because they take no interest in the Army as a whole. Many M.O.s—civilians conscripted into the Army—have joined up with antagonistic feelings to the Army, and have adopted an attitude of obstruction from the start. The "colleague in the Forces" sounds to me to be of this type. Yet in spite of these bad examples of our profession the Service has functioned well. Let me mention two examples of good organization. I have known a hospital of 1,200 beds empty itself of patients, move over 300 miles, and be ready to fill its beds again within 2 to 3 weeks. On an assault landing surgical teams were operating on shore within 8 hours of zero hour, and earlier casualties were receiving treatment on a hospital ship.

Now I will answer some of the points raised by my colleague. Concerning "the heavier burdens of civilian life in comfort, transport, and relaxation (especially alcohol)." I would like to point out that on the Anzio beach-head, where I am writing this letter, and where medical units have been working for nearly 4 months, comfort and relaxation are minimal, transport is of little use, and the supply of "alcohol" is within very narrow limits. The food is very good and well prepared, but I would still prefer a civilian ration cooked by my wife in my own home.

As regards confidential reports, there are two types—an adverse report which must be shown first to the officer concerned, and a recommendation for promotion, which for obvious reasons is confidential. Remarks about medium reports, etc., merely show the ignorance of my colleague on the subject. Also promotion for medical officers is rare within a unit, so that there is no petty rivalry between fellow officers on this account.

The hospital referred to seems to be having a very slack time indeed (a state of affairs I found difficult to fit in with the shortage of catgut). How much time per day does this officer devote to training his underworked orderlies to a higher standard of work for when their time comes? Or are they all perfect nursing orderlies? It must be remembered that the assessment of numbers of sick and wounded is extremely difficult, and that preparations must be made for the maximum number. I have known cases where the Service has been considerably strained, especially in isolated areas, but it has never broken down.

I have heard so much nonsense about Army Forms, with which I once agreed, but when they are carefully looked into there is a reason for each one of them. For my own personal needs I probably have to fill in many fewer forms than my wife, and I know that I have far less medical "clerking" to do than when I was an R.M.O. at a civilian maternity hospital.

I am 100% in favour of a State Medical Service, though not one run on exactly Army lines, because it will be dealing with different problems. I feel sure it will come and have grave doubts of its initial success. These doubts, however, are mainly fears for what our profession will do to make it a failure.—I am, etc.,

T. EDWIN HALL,
Capt., R.A.M.C.

Spanish Medicine

SIR.—In your annotation on Spanish medicine (June 17, p. 820) you say: "Spanish has not hitherto been regarded as a medically or scientifically important language, but in Argentina, Mexico, Chile, and elsewhere in the Spanish-speaking world, active centres of medical investigation exist or are developing, and it seems not unreasonable to suppose that Spanish will in the future achieve an important position . . . as a medium for the communication of discoveries in medicine and other scientific fields." This statement does substantially less than justice to the outstanding researches in the last twenty years in physiology and experimental medicine of B. A. Houssay of Buenos Aires and his past and present collaborators like Braun-Menendez and Orias. The contributions of the Houssay school in all fields of endocrinology are of outstanding importance; I need only refer to their discovery of the diabetogenic hormone of the anterior pituitary, which has revolutionized our views on carbohydrate metabolism and diabetes mellitus. The periodic reviews which Houssay has contributed to American journals reveal a wealth of significant advances made by his school in connexion with the physiology of all the ductless glands. The Houssay school are also responsible for our current interpretation of Goldblatt's work on experimental ischaemic hypertension; a recent monograph on the subject from the Argentine is well worth

translating into English. The monograph by Braun-Menendez and Orias on the heart sounds has been translated into English, and has been highly appreciated. It would be as well if you could arrange for authoritative informative reviews of the important work of Argentine medical scientists to be made available more often to their colleagues in this country.—I am, etc.,

SAMSON WRIGHT.

* * We think that a careful reading of the annotation shows that we fully recognize the importance of Argentina as an active centre of medical investigation. Prof. Wright's reference to the work of B. A. Houssay may be supplemented by the observation that in 1942 we invited Prof. Houssay to write an article for the *Journal* on renin, and a paper entitled "The Role of Renin in Experimental Hypertension," by B. A. Houssay and E. Braun-Menendez, appeared in the opening pages of our issue of August 15 in that year.—ED., B.M.J.

Colonial Medical Service

SIR.—I would like to have an opportunity of saying that my remarks on the above Service have been unfairly and unjustly misinterpreted. The strictures of my censors are quite unjustified. It was never my intention to "cast a slur" on the medical personnel of the Colonial Service, collectively or individually, in a general disparagement. I know too well the very fine, praiseworthy professional work which has been done continuously, sometimes under most unfavourable conditions, in many Colonies. Indeed, in previous observations in the House of Commons in Colonial debates I had praised without stint such excellent efforts, as, for example, when I singled out for special approbation the estimable work of the medical officers in Caribbean ports who had by their superb vigilance kept certain epidemic diseases from the West Indies. My castigation was intended for the administration, organization, set-up, and general conditions of the Service from the aspect of an overriding medical bureaucracy, without Whitley Councils, or negotiating or arbitrating machinery, or organizational representation in past years. On that I am prepared to stick to my guns and to defend my remark, which was made in the debate on the proposed British health reorganization, and which was not challenged by any opposing M.P. at the time.

I hope this disclaimer will stop the twisted interpretation of my Commons sentences in one debate. My professional friends and colleagues in many Colonies are fully aware of my admiration for their devoted medical work, and my B.M.A. constituents in the West Indies especially will recognize the prejudices of my critics. A criticism of any Service has never previously meant a disparagement of its personnel. This line of argument would stultify any unfavourable comment on any Government Department or administration. Lord Hailey is concerned with the effect of my remark on the recruitment to the Colonial Service from "the medical profession in this country, which must provide the personnel for its expansion." I am keener on properly organized recruitment, not on *Herrenvolk* lines but on merit and qualifications, without regard to colour, race, or creed, carefully vetted by an independent advisory professional Colonial Appointments Board, with a preferential tendency towards native-born talent if available and up to the required standard.

I hope my language here is suitably reserved as compared with the over-emphasized abuse of my chagrined critics.—I am, etc.,

House of Commons

H. B. MORGAN.

SIR.—Your correspondents have so far praised the organization of this service and its British medical personnel. Hardly a word has been said about the native Colonial peoples for whom the Service is intended. Research is, of course, indispensable to progress, but since the results of its findings bear a reference to the future, the merits of the Colonial Medical Service have to be judged not merely in terms of the satisfaction which it derives from its own efficiency but also in terms of its immediate effects on Colonial health and welfare. Some pertinent questions suggest themselves:

1. Is the relation between doctor and native patient personal? Is any such relation possible without a knowledge of the patient's

language and/or some intimacy with his cultural background? Is there free choice?

2. What is the ratio of doctors, or of hospital beds and welfare centres, to the population of each colony? What is the infant and adult mortality rate? Is there health insurance of any kind?

3. Are fully qualified natives engaged on a basis of equality? Is the expansion of the Colonial Medical Service conceived merely in terms of increasing the number of European doctors and native auxiliaries respectively?

4. Is the Colonial Medical Service a subsidiary branch of the colonial political system? Do the native colonials possess any effective democratic control over the political structure?

When these questions have been fully answered it will soon be obvious whether or not Dr. Morgan's condemnation is justifiable.—I am, etc.,

Chesham.

S. D. CUDJOE.

SIR.—Evidently Dr. Columba Guest (June 10, p. 797) sees the medical world split sharply into two camps: the noble altruists of the Service and the mercenary "diehards" whom nought but a fee will galvanize into activity.

This goes too far. For, on the one hand, my various friends serving in the Colonies (where living costs are low for the most part) assure me that they are adequately paid and pensioned—I should infer as much in any event from the favourite words "Efficiency Bar at £850," which, incidentally, hint delicately at that problem confronting so many services: a certain tendency to resting upon oars. And, on the other hand, I see so many consultants working many hours a day for nothing, and not entirely in institutions, while most of us can remember the G.P. of the old school whose fee was his last concern—a means whereby to live but not an end in life. Nor is he yet quite dead, and if his day is passing it is mainly because changed economic conditions render his unpaid work at once less essential to his patients and a matter of more difficulty to himself. Times change and we with them.

But there are still times when fees should be waived, and I prefer to think they still sometimes are forgone. This represents a real sacrifice on the part of the private practitioner, for he has neither the backing of a regular salary nor the expectation of a coming pension.

We are short of good men here as well as in our Colonies. And it seems a pity that so many ardent medical reformers are like Dickens's character Mrs. Jellyby. With "their fine eyes" on Africa they fail to see that there is plenty of scope for missionary zeal and the crusading spirit in the place where humanity proverbially starts work—at home.—I am, etc.,

Wingham

PETER PARRY.

Medical Research and General Practice

SIR.—The article by Dr. C. E. S. Flemming on research and general practice (June 3, p. 759) encourages me to write to you on the same subject.

Organized medical research in this country is undertaken partly by the Medical Research Council's workers, partly by research departments in some of the large teaching hospitals, and by the research departments of a few of the large industrial concerns. The number of permanent posts which can be obtained in such work is extremely small. The majority of research workers receive grants or scholarships or salaries which compare very unfavourably with the remuneration that an average general practitioner expects to earn. The future is relatively insecure for the research workers, since their grant may last 2 or 3 years and then terminate, and a fresh grant may not be obtainable.

As a result of these conditions many doctors who are suited in temperament and in mental ability to a life of research gradually drift into general practice. Most general practitioners are too busy to spend much time in study, and no facilities exist from which they could easily obtain help and advice should they wish to explore a suitable field in clinical medicine.

One of the chief benefits to the doctor which may accrue from practising in a health centre as a member of a team instead of working a single-handed practice will surely be that facilities for clinical research will be much more readily available. More cases of the type that interests him should be forthcoming, for his colleagues will probably refer such cases

to him for an opinion. Moreover, he will have at his back a pathology department equipped for simple routine tests, and this will enable his observations to be more scientific and less the result of guesswork.

If such research became at all common, advice centres might be set up in suitable teaching hospitals to guide the practitioner in his choice of subject and in his methods of work. The multiplication of research results which would follow would surely be of great ultimate value to medicine. At present, study is largely limited to work on cases of advanced disease, since it is these cases almost entirely which are sent to the large hospitals where research is carried on. The first stages of disease are seen by the general practitioners only. As a result, organized study of the important first stages of disease is largely lacking. A new phase in the study of disease might open if the general practitioner, suitably equipped and with expert guidance available, were given an opportunity to continue his studies, begun during his training, right through his career.—I am, etc.,

Wem, Salop

MARY E. YUILL.

"Departmental Prescription"

SIR.—You are taken to task by Dr. W. F. Annand (June 17, p. 827) for "snarling at the Minister of Health." You are reproved for failing to realize "that the Minister is working in the interests of the community, and that those of the doctors are of small importance in comparison." And you are adjured to give the Minister credit for a single-minded belief that his proposals are in the public interest; "after all, he is advised by expert medical men."

A growl of protest at these ingenuous views may be permitted, bearing in mind that if criticism of Government proposals is offensive to some minds, snarling is to others an objectionable term. Dr. Annand fails to give due consideration to the fact that large numbers of his colleagues share a single-minded belief that these proposals are very far from being in the public interest and deem it imperative to say so. Despite official denials, they do see in these proposals a desire to control an independent profession in order to control medical certification. They regard any such tendency in policy as a menace to the public interest and to the preservation of professional standards, both ethical and material. They hold that the interests of the community are not best served by attaching small importance to those of the doctors. And for so thinking they have very solid grounds indeed.

Dr. Annand concedes that the Minister may be mistaken—"misguided"—although advised by experts. Many share this view, as your columns, Sir, bear witness. In National Health Insurance matters the attitude of the Ministry, since its inception, has been narrow, stultifying, and repressive. Dr. Dain on June 1 at Bristol, put it on record that the profession "had experienced the futility of attempting to influence the development of the insurance service. Representations made over and over again for the enlargement and improvement of the service had fallen on deaf ears." He referred to the Insurance Act Committee and its continual struggle with the Government to obtain suitable remuneration.

The issues raised in the White Paper for a comprehensive health service are wide, and far more is at stake for the public and for the profession than appears on the surface. Dr. Annand concludes that the whole is always greater than the part. Quite so; let us scrutinize the parts now, however, building only on secure foundations.—I am, etc.,

High Wycombe, Bucks.

DOUGLAS J. B. WILSON.

The National Maternity Report: Correction

SIR.—In the report on a National Maternity Service just published by this College a most regrettable mistake has occurred. On page 5 in Table II a maternal mortality rate of 3.6 per 1,000 is given to Birmingham. This is wrong. For "Birmingham" read "Blackburn." I and my colleagues deeply regret having done this disservice to the fair fame of a city whose records for maternity and other health services have always stood so high.—I am, etc.,

EARLDFY HOLLAND,
President, Royal College of Obstetricians
and Gynaecologists

Obituary

J. HUGH THURSFIELD, D.M., F.R.C.P.

Consulting Physician, St. Bartholomew's and Great Ormond Street Hospitals

Born in July, 1869, Hugh Thursfield, who died on June 20, was the eldest son of Dr. T. W. Thursfield, F.R.C.P., at one time a physician of eminence at Leamington Spa. He was at school at Leamington College, and with a classical exhibition he went up to Trinity College, Oxford, where he obtained an honours degree in Greats. Thereafter he became a student at St. Bartholomew's Hospital, and later obtained the Oxford degrees of M.A. and D.M. in 1897 and 1899 respectively. At St. Bartholomew's he was for many years a demonstrator in morbid anatomy, and in 1909 published jointly with Dr. W. P. S. Branson a volume on *Medical Morbid Anatomy and Pathology*. With his election as assistant physician at St. Bartholomew's and the Hospital for Sick Children, Great Ormond Street, his professional career was fully established. At both hospitals he worked until he reached the age limit for active service, but at St. Bartholomew's, unfortunately for him, his retirement became due before there was a vacancy for him on the senior staff. His Fellowship of the Royal College of Physicians dated from 1906, and he was a member of the Council from 1929 to 1931. During the period 1910-26 he held various posts of honour in the Sections of Pathology and of Children's Diseases at the Annual Meetings of the British Medical Association.

Although he had an extensive knowledge of general medicine and medical pathology his chief interest was in his work at Great Ormond Street, and his most important literary activities were in connexion with paediatrics. He was, with the late Sir Archibald Garrod and Dr. F. E. Batten, an original editor of the well-known book *Diseases of Children*, published in 1913, and was responsible for its latest edition with Dr. Donald Paterson. Also he was the first co-editor of the *Archives of Disease in Childhood*, founded by the British Medical Association in 1926. The original editors continued in charge for eight years; and it was through Thursfield that the policy was adopted to publish only original work in paediatrics. This policy gave publicity to valuable contributions for which no other outlet existed, and it is impossible to doubt that this has had its effect on the English school of paediatrics.

At the age of 66 he retired from London, and finding a house and garden which just suited him near Basingstoke he settled in with great happiness. Early in the war he was appointed physician to Park Pretwell E.M.S. Hospital, Basingstoke, which post he still held at the time of his fatal illness.

Thursfield was a bachelor and exhibited the best traits of that state. Among these was a great gift for keeping in touch with people, so that his circle of friends was most extensive. So, too, were his intellectual interests. Coloured by his classical education, his devotion to Oxford, his work at two important hospitals, and his long membership of the Athenaeum, he had an immense fund of knowledge at his disposal. He was much more than merely well read in prose and verse, and himself wrote the simplest and most accurate prose. The very strong discipline which he maintained over his own literary language was perhaps compensated for by his love for words themselves, their histories and developments. He had an expert knowledge of English birds, and was a rare connoisseur of red wines. But in addition to such special subjects—and others might be mentioned—his general knowledge was quite remarkable. Mixing once more in the last years of his life with many men so much younger than himself, his encyclopaedic knowledge became not only a convenience but a source of pride to the hospital. He would surprise a radiologist by detailing the history of the invention, and development of the dynamo; and without hesitation give a complete list of the signs of the Zodiac, or the dates and publishers of all the earlier editions of the *Encyclopaedia Britannica*. How or why he remembered such things was not divulged; yet he had never a good word for his memory! He was more interested in facts than in theories, but seldom gave full assent to any opinion expressed

before him. His method of meeting such a situation was highly characteristic. He would propound some opposing view, courteously and in no spirit of criticism or controversy; it appeared as an alternative suggestion which his opponent might care to consider, and there it was left. As a man of decided views this was an example of his wide tolerance for others: he assumed an honesty of purpose and that sufficed. One other great note of his character was his equanimity. He was never out of temper, never even ruffled, and he was ever ready to excuse faults which he would not wittingly have tolerated in himself.

Thursfield held the view that a memoir should deal more with the personality than with the career of its subject. It did not occur to him that in some instances the writer might encounter special difficulties in what is at best an unhappy business! In his own case there are no such difficulties: nothing to be glossed over, nothing to be suppressed. The chief notes of his straightforward character were truthfulness and tolerance, and for these he earned men's high regard.

J. SHAW DUNN, M.D., M.Sc.

Professor of Pathology, Glasgow University

John Shaw Dunn was one of the most eminent pathologists of his generation. Temperamentally a naturalist, his powers of observation were sharpened early by ranging over his native countryside in Ayrshire and on the streams and lochs where he loved to fish. Like many others, he owed much to the Department of Pathology of Glasgow University and Western Infirmary, where he became successively student, assistant, and lecturer with Prof. Robert Muir. The individuality of his bent soon declared itself in the pursuit of problems which he made peculiarly his own, and it is of the chief of his many contributions to medical science that I wish to speak here. The first of these was the demonstration, along with J. W. McNee, of the pathological nature and mode of spread of gas gangrene, which was investigated at a mobile laboratory in France during the war of 1914-18 (published in this *Journal*, June 2, 1917). It was shown that gas gangrene is a disease of muscles and tends to spread in their long axis, so that single muscles are involved from end to end, while neighbouring ones are untouched. The essential materials used in this work were limbs amputated for gas gangrene and brought to the laboratory while the healthy muscles were still contractile. As a direct result there followed the successful conservative treatment of early gas gangrene by the resection of infected muscles. This revolutionary procedure spared many wounded men the mutilation of the older method of high amputation.

After the war Shaw Dunn took up studies arising out of trench nephritis, which he followed with undivided and indefatigable enthusiasm for over twenty years along with numerous younger workers. He determined to bridge the gulf between the clinicians' and the pathologists' conceptions of nephritis by relating disturbances of renal function to the underlying structural changes. Throughout this period much experimental work was carried out on nephritis produced by chemical substances such as oxalates. In particular, he followed the functional damage over considerable periods, and showed how the ultimate fate of a nephritic animal might depend on its intake of water sufficing to ensure the necessary excretion of nitrogenous waste products. But failure to reproduce that type of primary glomerulo-nephritis which so often characterizes the initial lesion in the human disease led him to concentrate attention on the state of the glomeruli in various acute and subacute renal disturbances. By Mallory's method of staining he detected as the essential lesion abnormal hyaline thickening of the capillary walls and patency of their lumina, which had hitherto escaped attention. Further, he set himself to apply the modern theory of secretion of urine propounded by Cushny to the phenomena presented by subacute glomerulo-nephritis, lipid nephrosis, and a proportion of pregnancy nephritis, where there is hydraemia with oedema but the related oliguria is associated with little or no impairment of the excretion of urea. In order to explain these conditions it is necessary to postulate, as Shaw Dunn showed, that the nephrons, because they are permanently dilated, must act continuously instead of with the normal intermittency exhibited in health; also they will be somewhat permeable to protein. At the same time,

Medical Notes in Parliament

Certificates for Special Foods

Sir ERNEST GRAHAM-LITTLE reported on June 8 that there was an official requirement that doctors issuing certificates for patients requiring certain special foods must give the clinical and biochemical data on which the diagnosis was based, and that certificates so completed were required to be submitted to the local food committee, so that a lay body was charged with revision of the medical certificate and was put into possession of details concerning the patient involving a breach of professional confidence. Col. LLEWELLIN said Sir Ernest was misinformed. Arrangements for granting extra or special foods to invalids were such that either the foods were immediately made available against a medical certificate stating only the medical condition of the applicant, or, where the medical certificate had, at the request of the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council, to contain the clinical and biochemical details on which the diagnosis was based, it was at once transmitted, through the agency of the Ministry of Food and its local offices, to that committee for consideration. At no stage was a detailed medical certificate submitted to a local food control committee or any other lay body for consideration or revision. The procedure had recently been re-examined by the Ministry of Food and approved by the Food Rationing (Special Diets) Advisory Committee.

Discussions with Socialist Medical Association

Sir ERNEST GRAHAM-LITTLE asked on June 8 whether the Minister of Health, in preparation of his Bill determining the future conditions of medical practice, had consulted, or proposed to consult, the body calling itself the Socialist Medical Association. Mr. WILLINK answered that he had not had any discussions with this association since the issue of the White Paper, but would, of course, be glad to do so if it wished. He was anxious to hear the views of all concerned before the stage of legislation.

Wartime Diet and Health

Col. LLEWELLIN on June 9 opened a debate on the Estimates for the Ministry of Food. He said the country would be able to maintain existing ration scales in everything for the rest of the year, except in milk, which had a seasonal variation. Despite increased military traffic on railways and roads, food supplies were getting through well, and there had been no call on the emergency supplies which had been laid in. He had undertaken to make, during the earlier stages of the liberation of Southern and Western Europe, a generous contribution towards the foodstuffs which the combined military authorities assessed as necessary for the liberated peoples. It would be absurd for this country, which was itself an importer, to make long-term provision of foodstuffs for Europe, or to cut down our reduced standard of living so that this provision could be made. The evidence available showed that in the United Kingdom national health had been maintained. There was no general loss of weight. Adolescents showed an increase, but there was some sign of a loss of the "middle-aged spread." There was no sign of impaired resistance to infectious diseases. Infant mortality reached its lowest level in 1942, and had maintained the same rate last year. Nevertheless the nation had been on a little-varied diet for some time, and more variety would be good. He would have to reduce on June 18 the milk allowance, though not to priority consumers, from four pints to three pints a week. He hoped to restore the cheese ration to three ounces before winter. Soft fruit would be short. It was impossible to carry fresh fruit about the country and distribute it evenly. He hoped to get oranges from Palestine, South Africa, and Spain. The Ministry was bringing in 17,000 tons of lemons, and he hoped to keep up that supply next year. This year he hoped to get apples from Canada, dates from Iraq, raisins from Cyprus, and 32,000 tons of Turkish dried fruit. Bread was better. The oats, rye, and barley had gone from it, and the only cereal in the loaf was wheat. The next four years would be a period of world shortage in dairy products and meat. We must produce as much as possible of these at home. He desired to see the National Milk Scheme and the milk-in-schools scheme continued, but to discontinue milk rationing and meat rationing as soon as possible after the war. The orange-juice scheme had been a success with mothers and young children. The take-up was well over 50%. He wished to see this continued after the war.

Mr. WILFRED ROBERTS said that some doctors were not happy about national health. There had been an improvement during

the war, but there were signs last winter that the health of the country was not so good. One local survey found symptoms of rickets in 10% of infants. Better distribution of more standardized vitamins would meet the problem. Doctors also criticized the fats position. Wartime rationalization made it difficult for people to get the purer grades of milk.

Col. ELLIOT said the health of the country was not so good as the figures seemed to indicate. People drove themselves to work, which diminished the sickness statistics. One could not feel happy about the tuberculosis statistics, especially in Scotland. Greater variety of food was needed. Lady APSLEY said the Government should make sure that children were not deprived of cod-liver oil and fruit juices through the ignorance or laziness of their mothers. National bread had improved the children's teeth and should be retained in use after the war. Mr. WOOTTON-DAVIES contended that the issue of fruit juices and vitamins should be continued to children up to the age of 7 instead of 5. Sir Henry MORRIS-JONES considered that all could do with more protein. People did not now recover so rapidly and readily from illnesses.

Administration of Milk Regulations

In the House of Commons on June 13 the Food and Drugs (Milk and Dairies) Bill passed through the Committee stage. A long debate took place on an amendment to Clause 1, moved by Mr. ERSKINE HILL, which, he said, would ensure that a dairy farmer was not struck off the register or refused registration solely because, in the opinion of the Minister of Agriculture (which meant in the opinion of his servants), the regulations would not be complied with. The amendment provided that the dairy farmer could only be removed on proof of some definite act or fault on his part. A right of appeal to an independent Court was asked for. In reply Mr. HUDSON, Minister of Agriculture, said the Bill was designed to try to improve the milk supply. The system which had been in operation under the Ministry of Health and the local authorities for the last 10 or 15 years had failed completely to achieve this purpose, and the Government had decided that a new system ought to be tried. This was the new system. They were concerned to secure, if it was humanly possible, the children of this country from the danger of drinking unsafe or unclean milk. All the clause was designed to do was to ensure that a man should not be registered, coming new into the industry, for the provision of milk for sale to human beings unless he fulfilled certain minimum standards. If the Minister of Agriculture was made responsible for the production of clean milk he must be given the necessary powers. To meet the question of an appeal, he proposed to ask the Milk Marketing Board and the National Farmers' Union to nominate a series of panels, consisting of his superintendent veterinary officer for the region and one member from both of the two nominating bodies. To these panels the dairy farmer could appeal if he disagreed with the recommendation of the Ministry's inspector. If a panel's decision was unanimous he (the Minister) would accept it. The amendment was negatived.

During a further discussion Mr. HUDSON undertook to set up county advisory committees, which should consist, broadly speaking, of his veterinary representative, probably someone with the qualifications of a sanitary inspector, the medical officer of health for the county, and some representatives of the local authority, the smaller authorities, and representatives of the Milk Marketing Board and the National Farmers' Union. These committees would act as general supervisory committees over the administration of the milk regulations in the particular counties. He also proposed to set up a central advisory committee in London, containing representatives from the various county committees.

Horton Hospital

On June 13 in the House of Lords the EARL OF CORK AND ORRERY drew attention to the conditions with regard to food under which military patients lived in Horton Hospital, Epsom. He said he was not making any direct attack on the hospital and certainly not on the medical treatment which the patients received, for that, he understood, was first-class. The chief complaints he had heard had been in regard to the quantity and quality and the service of food. He had heard of overcrowding in certain wards, inattention to the patients, and a general want of system in the whole administration.

Viscount DAWSON OF PENN said it was admitted that the feeding arrangements at Horton had not been satisfactory. The actual building was good, but it was never meant for a hospital in the ordinary sense of the word; it was a place for mental patients in the old days. The hospital was spread out—it was almost a Sabbath-day's journey to go from one part of it to another—and the only way to provide hot food in some of the more distant wards would be by means of trolleys. This hospital was one of the best. He was not talking of the culinary side

of it, but the hospital was reckoned by those of them who knew it as one of the best hospitals for good work for the sick and wounded that they knew of.

The EARL OF MUNSTER said that Horton Hospital was administered by the London County Council under arrangements made with the Ministry of Health, and general supervision was exercised by the Ministry to ensure that the treatment and welfare of the patients were satisfactory. It was one of the largest E.M.S. hospitals in the country and could accommodate 2,300 patients. Some of the wards were a very considerable distance from the main kitchens, which had, in addition, to cater for the patients and the staff as a whole. Consequently the facilities for cooking and serving meals were very inferior to those which would be met in a normal general hospital. Horton was visited under the new scheme of inspection in February last, and it was found that the general standard of the feeding arrangements was not satisfactory. A further visit was made to the hospital on May 30 by officers of the Ministry of Health and Ministry of Labour, and although the feeding arrangements were then found to have been much improved it was clear that further action was still needed. As a result steps were taken by the L.C.C. to introduce a greater variety into the menus, and a catering administrator was to be appointed at once. Taking into account that many of the patients would be on low diet, it was thought that with appropriate management and avoidance of waste the civilian rations in hospitals receiving a substantial number of Service patients should suffice. Service men, however, had been accustomed to considerably larger meat rations, and it had been agreed that provision should be made for a necessary margin. Measures were being taken to increase the kitchen and administrative staffs. New gas grills were being laid, and electrical equipments were being fitted to some trolleys. Extra machines for the preparation of food and twelve refrigerators were being installed. There was some justification for the complaints which had been made but it was hoped that these difficulties would finally be resolved.

Vaccination in Gibraltar

Mr. VIAN on June 13 asked the Secretary of State for the Colonies whether Rule 5 of the temporary rules for the vaccination of people resident in Gibraltar during the outbreak of smallpox in February and March contained any recognition of conscientious objection to vaccination; and what authority existed for imposing vaccination on persons leaving a colony. Col. STANLEY said that Rule 5 did not make vaccination compulsory, its effect was simply to make it clear that persons who had not been vaccinated might not leave Gibraltar. The absence therefore, of the element of compulsion made unnecessary, in this particular rule, any reference to the recognition of the rights of conscientious objectors. The rules were made by the Governor under the authority conferred on him by Section 209 of the Gibraltar Public Health Ordinance.

Scottish Health Services

The House of Commons, in Committee, discussed the estimates for the Housing and Health Services for Scotland on June 20. Mr. JOHNSTON said he had asked for a comparative table of health statistics, and the Chief Medical Officer of Health for Scotland had reported that, in spite of the strains and stresses of four years of war, by and large the health of the people of Scotland, despite a breach in the wall here and there, was better than in the last pre-war year. The number of live births was up by 12%. The death rate was up 0.7 per 1,000 of the population compared with the last pre-war year. Since 1939 the figures for stillbirths had been reduced by 6 per 1,000 of the total population and there was a steady decline year after year. Compared with 1938 the maternal mortality figure was down by 1.2 per 1,000 live births. In 1938 the maternal deaths totalled 432 in 1943 364, and year after year the rate was coming down however slowly. The lowest rate for maternal mortality ever recorded in Scotland was in 1943—3.7 per 1,000 live births. The reduction in infant mortality—deaths under 1 year of age—in 1943, against 1938, was 4.3 per 1,000 live births. That rate was still too high, and was nearly one-third worse than the rate for England. The Scientific Advisory Committee was now considering the high proportion of neonatal deaths due to infections at home and in hospitals.

Infectious Diseases in Scotland

With regard to the notification of infectious diseases, diphtheria notifications fell from 10,786 in 1938 to 9,255 in 1943. Scarlet-fever notifications were down about 4,500. Measles and whooping-cough showed a remarkable reduction, being down from 33,000 in 1938 to 23,000 in 1943. In 1938 diphtheria deaths among children totalled 430, but in 1943 they were only 195. Immunized children showed only one death in every 163 cases, while non-immunized children showed one

death in 18. Pressure was still going on to increase the number of children immunized in schools. Notifications of cerebrospinal fever had fallen 55% since 1940. Here, again, the Department expected a report from the Scientific Advisory Committee on treatment by sulphonamide drugs. The fatality rate for cerebrospinal fever had fallen, it was alleged, by 50% as a result of this treatment by sulphonamide drugs.

In the enteric group of diseases typhoid and paratyphoid A and B, taken together, showed that notifications were down by one half since 1938. There were 268 notifications of typhoid in 1938 and 160 in 1943. There were no notifications of paratyphoid A in 1943, and 60 of paratyphoid B. There were more dysentery notifications than in 1938. This problem apparently was also exercising the authorities in England. The Scientific Advisory Committee—Sir John Orr's committee—with Prof. Mackie as chairman of the subcommittee, was reviewing the available evidence about the cause or causes of this increase in dysentery. In 1938 there were 2,648 cases of dysentery, and in 1943 3,425 cases. There was only one case of smallpox in 1943.

Venereal disease was a very difficult subject, on which there was a great deal of difference of opinion, both about methods of treatment and the powers that ought to be given to local authorities. The question of notification covered a vast field of dispute. The Church of Scotland had come down strongly on the side of compulsory notification. Some of the other Churches were against compulsory notification, but a large number were with the local authorities, in favour. The Department were in contact with all these bodies, and they were trying to reach the maximum amount of common agreement preliminary to coming to the House of Commons. The report of the Committee of Inquiry showed that in 1938 new cases of syphilis under treatment at clinics rose from 2,990 in that year to 4,841 in 1943. In 1938 there were 5,133 cases of gonorrhoea, and in 1943 5,437.

Notifications of pulmonary and non pulmonary tuberculosis were on the increase having risen from 7,565 in 1938 to 10,088 in 1943. The figures for the first quarter of 1944 showed a diminution—it might be only temporary—against the first quarter of last year. In 1938 there were 3,431 deaths from tuberculosis, and 3,949 in 1943 an increase of about 520. They had been able substantially to increase the number of beds in tuberculosis institutions in Scotland, from their civil defence hospitals, from 5,300 beds to 6,300. The real difficulty was not the beds but the provision of nurses and domestic staffs in these hospitals. Many institutions were grievously short of these. The number of probationer nurses was increasing, but not sufficiently to meet the demand. The Department had taken the best advice they could on the question of nurses from medical men and the nursing associations, but obviously the Minister of Labour would hesitate to direct civilian employees compulsorily into T.B. institutions. The Advisory Council were opposed to compulsion on the ground that they would not get the right type of nurses in that way, and that if they did the nurses they got would not be too friendly disposed, and their presence might do more harm to the patients than otherwise.

The Department had done everything possible to appeal for part-time volunteers. There were only two additional sources which he thought they could tap one was the Women's Voluntary Service, the other suggestion, made by Dr. Laidlaw of Glasgow, was that some empty houses should be taken and used for sleeping accommodation for men who were otherwise fit and able to go to their work. This had been tried in Russia, he was told, with some considerable success, and he was prepared to try it if houses were available.

The best evidence of the improvement in health compared with 1938, Mr. Johnston said, was contained in the reports of the school medical officers on the weighing and measuring of school-children. These showed, by and large, that the health of Scotland was being maintained so far as women and children were concerned, although in regard to tuberculosis they went back. He hoped for considerable results from the Scottish Council of Health Education. The object was to encourage education in the science and art of healthy living and the principles of hygiene, and to assist local authorities in publicity or propaganda for health purposes.

The Housing Problem in Scotland

With regard to housing, Mr. Johnston said that over 75,000 war-damaged houses had been restored, and arrangements had been made to erect 2,000 new houses in specially badly hit areas. There were 600 shops or houses requisitioned and repaired as temporary dwelling-houses. There would be, although not immediately, some augmentation of the housing programme through the provision of steel houses of new and improved types. The Government was doing everything it could to

arrange for mass servicing of housing sites, providing water, drainage, roads, etc., for some 40,000 houses. He was doing his best to get 100,000 factory-made houses, of the emergency ten-year-life type, for Scotland:

Lieut.-Cmdr. HUTCHISON urged that the most essential single factor in the health of the nation was the provision of better housing conditions. That point, he said, was brought out very strongly in paragraph 7 of the paper issued by the British Medical Association on the national health services. He did not believe that any amount of organization or reorganization of the medical services would, by itself, bring about any improvement in the nation's health unless and until they had as a foundation-stone good sound houses, fitted with modern sanitation and proper water supplies.

Dr. ELLIOT said that the programme for permanent building was not enough, nor were the proposals for the labour supply to handle the materials adequate. Until the Portal house had been lived in it was not safe to say that it was a suitable house to put into flow production.

Mr. HUBBARD said that the conditions now existing in the maternity services should be taken seriously into consideration before those services were divided. The same thing applied to the services relating to infectious disease. The closest collaboration between the medical services, including the welfare service, should be explored before any alteration was made. The Department would be well advised to spend much more on preventive measures.

Major LLOYD, who emphasized the importance of the dental service, asked the Secretary of State, before committing himself to any future plans, to consult those best qualified to speak on the whole question of the medical, hospital, and allied services and their future administration.

Mr. WESTWOOD, replying to the debate, said that all the suggestions which had been made would receive serious consideration.

Nutrition in the Colonies

In a reply on June 21 to Mr. Creech Jones Col. STANLEY said that for some years now nutrition committees had been functioning in a large number of Colonies. Many had done valuable work. Following on the resolutions of the Hot Springs Conference, he communicated further with Colonial Governments as to their nutrition policy. The Medical Research Council recently formed a Human Nutrition Research Unit. This, under the direction of Dr. B. S. Platt, was engaged in investigations on colonial nutrition and offered hospitality for study and research to nutrition workers from the Colonies. The unit would also be ready to advise Colonial Governments on technical questions. Its formation was a first step towards a wider organization to include both teaching and research. He hoped that in the near future Dr. Platt would again visit certain Colonial territories to investigate the position and advise on future plans.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* measles and whooping-cough rose in incidence by 320 and 200 notifications respectively, but the totals for scarlet fever and acute pneumonia fell by 51 and 56.

The notifications of diphtheria were 1 fewer than the record low total of the preceding week. Lancashire notified 95 more cases of whooping-cough than last week, but London's total fell by 41. Measles notifications exceeded last week's totals in Lancashire by 93, in Northumberland by 65, in Wiltshire by 52, and in Southampton by 45, but the incidence fell in London and in Essex by 29 each, and in Middlesex by 24.

Dysentery notifications were 6 fewer than last week. The only new outbreak of any size was in Gloucestershire, Bristol C.B., 17. Other important centres of infection were London 38, Lancashire 27, and Derbyshire 12.

In *Scotland* there was a general diminution in the incidence of infectious diseases, the only exception being a rise of 39 in the notifications of diphtheria. There was a small rise in diphtheria notifications in most registration areas.

In *Eire* the total notifications of measles were 74 more than last week, and of diphtheria 34—the latter contributed mainly by Dublin C.B. A fourth case of typhus was recorded in Roscommon, Castlereagh R.D. Scabies is prevalent in Cork C.B.; the M.O.H. states that a conservative estimate would put the cases at 15,000 to 20,000.

Week Ending June 17

The notifications of infectious diseases in *England and Wales* during the week included: scarlet fever 1,544, whooping-cough 2,628, diphtheria 456, measles 2,623, acute pneumonia 490, cerebrospinal fever 38, dysentery 191, paratyphoid 5, typhoid 8.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 10.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

Once again this year the Derry Gardens, Kensington High Street, will be "open" on behalf of St Bartholomew's Hospital from Monday, July 3, to Friday, July 7, each day from 9.30 to 6. The gardens are worth viewing and the object is a good one.

An extra general meeting of the Middlesex County Medical Society will be held at the Royal Society of Medicine on Wednesday, July 5, at 4.30 p.m., when Sir Harold Gillies will read a paper on "The Province of Plastic Surgery in a Health Service". Visitors, including members of the American and Canadian Forces at present in this country, will be welcome.

The London Women's Parliament (24, High Holborn W.C.1) has arranged a conference on Sunday, July 9, at 3 p.m. at Conway Hall, 14, Lion Square, to discuss (a) how to get full- or part-time labour or hospital nurses, factory canteens, British restaurants, schools, nurseries, and home help schemes—all social services on which the future front depends; (b) how to improve wages, conditions, and social status so as to encourage women to take up domestic work and stay in the job.

At a meeting of the Danish Medical Society, Prof. K. A. Jensen of Copenhagen University recently reported that a Danish chemical factory was shortly to begin production of penicillin. The experiments were conducted by the pathological institute of the University.

The Committee on Nutrition Surveys, set up by the English Group of the Nutrition Society a year ago, has drawn up a list of investigations, recent or in progress, into: (1) consumption of food, (2) nutritional state, and (3) effect of supplements on health and efficiency. The number is unexpectedly large. A list of these investigations will be sent to anyone working on the subjects, on application to the Director, Prof. J. R. Marrack M.D., Advisory Committee on Nutrition Surveys, Bureau of Nutrition Surveys, London Hospital E.1.

The Colver Prize was founded in 1926 by the Royal Society of Medicine to commemorate the twenty-five years' service of Sir Frank Colver as honorary curator of the Odontological Museum, and regulations were approved. The accumulated income of the fund is ordinarily used every third year for a prize for the best original work in dental science completed during the previous five years by a dental surgeon educated at any recognized dental school in Great Britain or Northern Ireland who has not been qualified to practise more than five years at the date of the award. Applications from candidates, with a general account of their researches, should be submitted to the Colver Prize Committee, 1, Wimpole Street, London, W.1, by Oct. 1, 1944.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Arcturule Westcent London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over seas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Arcturule Westcent London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the ASSOCIATION, TELEPHONE: EUSTON 2111. TELEGRAMS: *Medicera Westcent London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Bronchitis in Children

Q.—*Latest I have observed that many children in the families I attend get frequent attacks of bronchitis. Would you recommend trying spraying the rooms and blankets with emulsified oil daily for a couple of months? If so, are special sprays and liquids recommended?*

A.—Bronchitis is a complication in about a third of attacks of the common cold. Children between the ages of 1 and 5 years are most addicted to colds, with an average of three to four a year. Therefore bronchitis is a common complaint among children. But colds in the spring or summer have a reputation for being more persistent than winter colds, and it may be that irritants such as dust predispose to bronchial involvement. Summer colds are also treated rather lightheartedly and children are not usually kept in an equable temperature until the acute corviza has gone. However, any measure that will minimize the dissemination of dust in the house is good hygiene, and for the purpose vacuum-cleaning of carpets, curtains, etc., damp dusting and damp sweeping (with tea leaves) of

polished surfaces, and, above all, good ventilation are strongly recommended, particularly in families where there are young children. Oiling of household bed linen is not at present practicable and spraying with emulsified oil is not advisable. To minimize blanket dust, the blankets may be sewn inside cotton sheets, or the Continental feather-blanket may be used instead. Another practical precaution would be to treat the floor of playroom or nursery with spindle oil (see M.R.C. War Memo No. 11, 1944).

Vaginal Pessaries

Q.—*Do vaginal pessaries containing quinine or lactic acid as the spermicidal factor cause a vulvitis vaginitis or cervicitis? If so, how is the inflammation prevented or treated?*

A.—Most chemicals which are spermicidal are irritant to the tissues when present in high concentration. The amount of active principle in contraceptive pessaries is therefore usually low. Even so, quinine pessaries, as sold, not infrequently cause severe vulvovaginitis and acute cervicitis in women who are susceptible. "Quinism" from absorption of the drug also occurs. Though lactic acid has a caustic action it is of low toxicity, and is a normal constituent of the vaginal "secretion". Moreover, pessaries usually contain only enough to counteract the alkalinity of the seminal fluid and to keep the vaginal pH within a normal range. They are therefore not so likely to have any irritant action on the vaginal epithelium and most women tolerate them well, cases of idiosyncrasy are comparatively rare. It is often stated in textbooks and elsewhere that the regular use of chemical contraceptives may result in such cervical lesions as erosion, chronic cervicitis, and endocervicitis. But this view appears to be based on general principles and on the known irritant action of these chemicals in high concentration. Definite proof has not yet been adduced to show that cervical lesions (and consequent sterility) have resulted from the use of chemical contraceptives, and the subject is one causing considerable dispute (see correspondence columns of the *Journal* June to December, 1943). However it remains a possibility, particularly in regard to the use of quinine.

The acute vulvovaginitis which sometimes follows the use of quinine pessaries usually responds quickly to simple treatment by rest in bed and warm baths. It is prevented by avoiding the use of pessaries containing quinine, which in any case, have a low spermicidal value, and on account of this and their irritant properties have been condemned by official opinion for some considerable time. Chinosol is said to be less irritant, but the results of scientific inquiry go to show that phenyl mercuric acetate is to be preferred (J. R. Baker and others, *Lancet* 1938, 2, 882). This has a high quotient of efficiency and is comparatively free from harmful effect, though on rare occasions reactions occur in either male or female partner when an idiosyncrasy to mercury exists.

Toxaemia in Pregnancy

Q.—*Mrs. H. 38, mother of two children (5 and 2 years) is anxious to have a third. In her first pregnancy albuminuria oedema of the ankles and some hypertension were present at the seventh month. Despite the usual treatment these signs increased markedly so that at term the urine was solid with albumin and the B.P. 190/100. The confinement itself was uneventful. Urine and B.P. returned to normal in two weeks. History of the second pregnancy is similar except that albuminuria etc. were present at the sixth month, that the highest recorded B.P. was 212/110 and that I induced labour uneventfully 10 days before term. What advice ought I to give? Would a urea-clearance test now be any guide to me?*

A.—This type of case is well known. The patients are usually over 30 at the time of the first pregnancy and the toxæmia develops relatively early. The condition recurs with subsequent pregnancies. The case described belongs to this clinical group. On the other hand both previous pregnancies proceeded to near term without abortion or premature labour, and after the first pregnancy the urine became clear of albumin. It is almost certain that the toxæmia will recur in a future pregnancy. On the other hand there is no reason to expect that the third attack will be more severe than the previous two. The risk is that of pregnancy toxæmia with the possibility of premature labour with a stillborn baby. It is doubtful whether a urea-clearance test will be of any help, for if the blood pressure and urine are normal the test will probably show normal values.

Red Hair and Rheumatism

Q.—*There is a widespread belief that people with red hair are especially susceptible to rheumatism and also to excessive bleeding. Is there any physiological or pathological basis for this? Indeed, is there any evidence for it?*

A.—There is undoubtedly a belief among physicians of experience that red haired persons are unduly susceptible to acute rheumatism. Shrubsole in a paper on physical characters and morbid predispositions made the striking observation that no less than 21% of a series of cases (28 out of 133) had red hair. This is far greater than the proportion in the general population in England, which is about

4%. Honeyburne,² however, did not confirm this result. He found that only 6.5% of a series of cases of acute rheumatism had red hair, compared with 5.2% in a control series (26 and 21 respectively out of 400). Further investigation would be well worth while. (It is perhaps an indication of the general lack of interest in the question of physical make-up and disease that in a copy of *St. Bartholomew's Hospital Reports* on the shelves of the Royal Society of Medicine, Shrubbsall's interesting paper had been reposing with uncut leaves for more than 40 years.) Should it be found that red-haired persons are even twice as susceptible as other people, so striking an association would be of much interest, and might well lead, as the question suggests, to physiological and pathological discoveries. Considerable numbers would be required, however. To demonstrate with reasonable certainty a difference in susceptibility of two to one, a series of acute rheumatics of the order of 500 would be needed. It would suffice to record simply whether each patient was red-haired or not. There seems to be no indication that it would be worth while investigating other differences in colouring. A control series of similar number would serve to remove any doubt as to variations in personal judgment of what constitutes red hair. I have no knowledge of any work on red hair and excessive bleeding. In the absence of data, is there not a suggestion here of the kind of false association upon which so many superstitions depend? I have even come across the peculiarly absurd belief that red hair is due to conception during the period of the menstrual flow.

Hairiness in a Woman

Q.—A married woman aged 35, with one child, complains bitterly of hairiness of the beard region and of arms and legs. Her menstrual history is normal. She states she is disinterested in intercourse and never gains satisfaction from it. Is endocrine therapy indicated in such a case, and what form should it take?

A.—If the hairiness began at puberty, and if there are no other endocrine stigmata, the condition is probably genetic and uninfluenced by endocrine therapy. In the presence of other features—e.g., adiposity, plethora, hypertension—one should investigate with a view to excluding an adrenal or ovarian tumour. In the case of Cushing's syndrome not due to an adrenal neoplasm, irradiation of the pituitary fossa is sometimes helpful. It is difficult to know how far the attitude to sexual intercourse is determined by the condition.

Sensitivity to Sulphonamides

Q.—What are the dangers of repeating a course of sulphonamide therapy? How can one distinguish the patient who is likely to be susceptible? What length of time is it advisable to leave between the courses? Are adults more likely to be susceptible than children?

A.—In the great majority of patients there are no such dangers. If no signs of intolerance have been observed during one course, they are unlikely to develop during a second, whatever the interval between them, and regardless of the patient's age. There should therefore be no hesitation in repeating a course when there are definite indications for it. On the other hand, early repetition implies previous failure, and if any doubt exists on these points it should be considered whether the treatment is correct or the dosage adequate. It is exceedingly uncommon for a patient to become sensitized to these drugs after administration by the mouth, though, as has recently been pointed out by Tate and Klorfajn (*Lancet*, 1944, 1, 39), this effect is very much more liable to follow local application.

Ant, Wasp, and Bee Stings

Q.—I have a patient who is hypersensitive to stings. Twice in one month he has been stung by an ant while gardening. He is quite fit, but the whole arm swells like a balloon. How can he be desensitized? I have given him a course of peptone injections. A wasp sting has little or no effect.

A.—Reports in the literature of allergy to ant bites are extremely rare, but reactions to bees, wasps, mosquitoes, fleas, lice, bedbugs, and chiggers frequently appear, and occasionally in this country cases of hypersensitivity to the bites of horse-flies. If the angio-neurotic oedema of the arm was definitely due to the bite of an ant (and not to, say, touching a primula) the reaction may have been due either to some specific chemical compound in the bite (such as formic acid, which also seems to play a part in the urticaria which follows nettle-stings), or more usually to a specific "ant" protein. This is analogous to what may happen in the case of bee stings, where some acute allergic reactions appear to be due to the pollen on which the bee has been feeding being injected into such a pollen-sensitive individual, but the majority of reactions occur in beekeepers and the like who have become sensitive to bee protein by recurrent stings and contact. In the treatment of insect sensitivity of whatever kind, the most successful therapy is not to get bitten or stung. But if this is unavoidable a sterile extract of the whole body of the

insect should be prepared, the patient's sensitivity to the extract always tested by skin test, and according to the degree of sensitivity elicited a course of desensitizing injections prepared. Such testing and treatment extracts can be obtained from Messrs. C. L. Bencard, Gorgate Hall, Dereham, Norfolk. Prince and Secrest (*J. Allergy*, 1939, 10, 379) have succeeded in protecting individuals sensitive to bee, wasp, or ant bites by using a whole-bee extract, and so believe that certain insect groups contain a common antigen. But I have not been able to confirm this observation.

Lichen Simplex

Q.—Could you advise me on the aetiology and treatment of lichen simplex? Could this condition be caused by chemical irritation, and is it the same condition as neurodermatitis? As lichen, I understand, is sometimes seen in those suffering from duodenal ulcer, is there any relation between the two conditions?

A.—Lichen simplex describes an itchy patch of skin thickened, pigmented, and quadrillated as the result of scratching. It develops primarily on the inner thighs and sides and nape of the neck; and secondarily, with a flexural distribution in the eczematoid eruption associated with asthma, a variety of the so-called neurodermatitis. Chemical irritation of the skin, if it induced scratching, might originate a patch of localized lichen simplex. There is no relation with duodenal ulcer except the psychological background common to both. An occlusive dressing, when practicable, cures by breaking a vicious circle. Otherwise a crude coal-tar paste may be prescribed, or x rays given with all the reservations called for in radiotherapy.

Thyroid for Premature Babies

Q.—Is it still generally accepted that large doses of thyroid should be given to premature babies, as advocated by Pritchard? If so, what doses may be employed without giving rise to toxic effects?

A.—Thyroid extract appears to have a beneficial effect upon a certain type of premature baby with a subnormal temperature, drowsiness, and reluctance to feed. It is given in maximum doses of 1/10 gr. per lb. body weight per day. A baby of 4 lb. can have, for example, 1/8 gr. b.d. or t.d.s. It should not be continued for more than a few days, and should be stopped if it does not seem to be improving the situation. Toxic manifestations do not occur with this dosage.

Nepenthe and Tinct. Opii

Q.—Can you tell me what advantage, if any, the drug nepenthe has over tinct. opii?

A.—Nepenthe is a trade preparation of opium containing 0.84% morphine in alcohol. It is used as an alternative to tinctura opii, which is slightly stronger, containing 1% of opium. I know of no difference in qualitative action, but nepenthe is more palatable.

LETTERS, NOTES, ETC.

Control of Crab Lice

Dr. RALPH JONES (London, W.11) writes: Within a day or so of reading Dr. K. Mellanby's memorandum on crab lice I ordered his prescription to a patient I considered very suitable for his method. I think it only right to warn your readers that there appears to be great difficulty (in London at any rate) in getting this prescription dispensed. I believe the trouble is that lanette wax is largely reserved by chemists for making benzyl benzoate emulsion. It looks as if, for the present at any rate, it will be more expedient in general practice to stick to the older methods.

Operation for Uretero-pelvic Stricture

Mr. J. B. MARINAN, F.R.C.S.Ed., medical superintendent, Dryburn Emergency Hospital, Durham, writes: I notice in your issue of June 10 a review of the 1943 *Year Book of Urology*, and a reference therein to a "new" operation for uretero-pelvic stricture. A similar manoeuvre was suggested by my then chief, E. S. Gawne, F.R.C.S.Ed., of Bolton, and used by us in a case of acute uretero-pelvic kink in a patient I investigated for him in 1935; the result was excellent. It seemed such an obvious procedure that we did not bother to publish it, and I should be surprised if some urologist in this country has not at least considered it.

Locked Twins

Dr. W. M. CHESNEY (Birmingham) writes: Mr. C. A. Horder's account in your issue of June 10 (p. 783) of a case of obstructed labour due to locked twins suggested the following observations: (1) As the membranes were still intact was the diagnosis of obstructed labour warranted in this case? (2) The amount of descent of the head of the first child at the time of intervention is not indicated, apart from the doubtful inference drawn from the position ascribed to the head of the second child. (3) Incidentally it is hoped that Mr. Horder is satisfied as to the accuracy of his informant's statement that full dilatation had existed for six hours; for it is well known that the adjective "full" is not infrequently used when dilatation is still incomplete.

A CLINICAL VIEW OF SHOCK*

BY

V. ZACHARY COPE, M.S., F.R.C.S.

Senior Surgeon St Mary's Hospital

Many words whose significance is well understood are difficult to define. This remark applies to the word "life" itself, and it is not surprising that shock, which threatens life and is the very shadow of death, should escape precise elucidation and definition. The difficulty is greater because similar symptoms may be produced by so many different agencies. The conditions induced by traumatic shock can be simulated by the effects of severe hæmorrhage by sudden loss of body fluid (as in cholera) by the introduction of foreign protein into the body by severe burns, by high voltage electric currents, by acute toxæmias, by some cases of visceral perforation, and even by severe mental stress.

Some critical observers have been so impressed by the absence of definite and easily measurable criteria of shock that they will accept no definition, and prefer to describe it by the enumeration of symptoms. Others have suggested different terms for the condition, such as "depressant syndrome," "traumatic hypodromia," or "exaemia," which give some indication of the pathological process involved. Shock is, however, a clinical state, and any definition must allow for the varied clinical picture which every clinical state may from time to time present. In any definition it is unwise to specify any particular symptom for the first thing the clinician should learn is that there is hardly one symptom of shock which is constant, yet by a careful consideration of all the symptoms it can almost always be decided whether or not shock is present. It is generally agreed that shock is associated with impending or actual failure of the peripheral circulation, and we might perhaps adopt as a safe working definition that "shock is a condition following the application of harmful stimuli, or the rapid depletion of the body fluids, in which there is a serious and clinically demonstrable depression of the vital processes of the body, particularly of the circulation."

In connexion with trauma it is customary to speak of primary and secondary shock—the former coming on immediately and the latter at an interval after the injury. Perhaps the terms "immediate" and "delayed" would be clinically preferable to indicate the immediate and delayed onset of shock. Immediate shock may last for only a short time unless the causative factors continue to act.

Clinical Symptoms

What are the main clinical symptoms of the shocked condition? A persistent reduced blood pressure is regarded by most investigators and clinicians as an essential feature of shock. They say, "No fall of blood pressure, no shock." Yet 30 years ago Parsons and Tyrrell Gray showed that clinical symptoms of shock might appear with a blood pressure that was still high, and in the last war Bayliss showed that a high blood pressure might persist with a small blood volume owing to powerful vasoconstriction. Recently Grant has called attention to the same phenomenon, and Meakins has emphasized the same point in a clear manner. The latter states "After the introduction of the sphygmomanometer our thoughts were slowly, ever so slowly, directed to the belief that a falling

blood pressure and shock were synonymous. This is to some degree correct, except that the real condition of shock has been initiated and has travelled well along its course before this spectacular and exact physiological disturbance occurs. It should be considered as one of the later findings to indicate the condition. It occurs after all compensatory mechanisms to maintain the circulation have failed."

Before we can tell whether the blood pressure has fallen we must know what it was before the injury, and there should be no need to be reminded that the average blood pressure for a given age may not be the normal for the patient. There are cases also, in which the failing circulation is shown more by the rise in diastolic than by the fall in systolic pressure. A low pulse pressure is probably a better indication of shock than a lowered systolic pressure. Even while the blood pressure remains high and before any serious symptoms have appeared shock may be present in a latent form. This *latent shock* corresponds to the time at which the compensatory vasoconstriction barely maintains the intravascular pressure, collapse may be precipitated by any further strain on the circulation—even turning the patient over may cause serious collapse. This clinical condition of latent shock must have been noted by most experienced surgeons but there is still need to emphasize its occurrence and its deceptive nature.

In well developed shock it will be agreed that its severity can best be measured by the amount of fall in blood pressure. If the systolic falls below 80 the condition is serious, and a pulse pressure of under 25 is of bad prognosis.

A *small weak and rapid pulse* is regarded as a necessary accompaniment of shock, yet it is now well recognized that serious shock may be present without any increase in the pulse rate. Many years ago Malcolm pointed out that the pulse rate might remain slow in shock but get gradually smaller until it failed altogether. Cuthbert Wallace in the last war noted a class of shocked men whose pulse remained slow, and the same phenomenon has been observed in the shocked air raid casualties of this war by Kelwick and others. From the operating surgeon's point of view I have confirmed that shock and a lowered blood pressure may coexist with a slow pulse. The testimony of so many observers must convince everyone of the not uncommon occurrence of shock accompanied by a slow pulse.

A *subnormal temperature* is a common symptom of shock, indeed I have come to regard this as one of the most constant features of the condition. Kinnaman's experiments on animals showed that a fall of temperature was a better guide to shock than a fall of blood pressure. Observation of air raid casualties led Kelwick and his fellow workers to say that the general temperature of all severe cases is invariably subnormal. The drop in temperature may be down to 95° or lower. This fall is not dependent upon the fall in blood pressure, for the metabolic processes of the body are not seriously affected until the blood pressure has fallen below 80 mm Hg, whereas it is common to get a temperature of 95° F in cases of immediate shock in which the blood pressure may be lowered but little or not at all. It may be that there is a definite inhibition of metabolic processes in shock. The immediate shock which may

* An abridgement of the Annual Oration to the Medical Society of London, delivered on May 8, 1944.

follow the perforation of a peptic ulcer frequently results in a temperature of 95° F. with pallor and cold extremities even though the blood pressure may be about normal or only lowered 10 or 15 mm. Hg. I think that those who deny that shock is often present in cases of perforated peptic ulcer take too narrow a view of the condition.

In cases of shock the skin is usually cold and pale or cyanotic, and sweating is often profuse. It is frequently the onset of these two symptoms which indicates to the surgeon that shock is present. If the cheek feels cold to the back of the observer's hand and if small beads of moisture appear on the forehead one knows that the patient on the operating table has had enough. Latent shock is becoming patent.

Mental dullness is a variable symptom in shock. It is quite true that many shocked patients are dull or stuporous, but others are mentally alert. It was said of the wounded at El Alamein that the mental state was usually one of alert interest even when the blood pressure was very low. It is difficult to account for these differences. It is important that we should diagnose shock before all the textbook symptoms have appeared. Shock may be indicated by a subnormal temperature with a low blood pressure although the pulse rate may be within the normal limits; it may reveal itself by pallor, sweating, subnormal temperature, and a small rapid pulse, while the blood pressure may remain approximately normal; and some cases occur in which the appearance and mental alertness give no indication of the serious state of the circulation which the sphygmomanometer may demonstrate. When a person has sustained injuries which are such as to be productive of shock one must assume its presence in a latent form even though no obvious symptoms are observed. The clinician must look at the whole picture before he pronounces judgment.

Pathology of Shock

Can the clinician throw any light on the vexed question of the pathology of shock? He is at a disadvantage with the experimental worker in that he cannot standardize his cases or furnish accurate controls; but clinical cases deal with human beings and usually present the important factor of pain in the causation of shock. Though Moon asserts that "conditions accompanied by prolonged and intolerable pain such as renal or biliary colic do not cause shock," most clinicians would consider this at the least too dogmatic a statement. Indeed, few clinicians could doubt that severe pain can initiate, accelerate, or aggravate shock.

Of the many theories put forward there are some which have little clinical support. Hyperventilation and acapnia could not apply to the majority of cases; acidosis is more likely to be the result than the cause of shock, and could not account for the immediate variety; the same remark could be made about the increase of blood potassium, which some, especially Scudder, regard as an important causative factor of shock. Fat embolism may produce symptoms almost indistinguishable from those of shock, but clinically it cannot be supported as a common cause of the condition. The suprarenal gland seems to play a part in causation of the symptoms, but as a rule those symptoms do not become evident until serious circulatory changes have already occurred.

All experimentalists agree that in cases of shock there is a serious diminution in the volume of blood in effective circulation, or, as Moon puts it, the volume of blood is relatively inadequate to fill the vessels. This fact is daily verified by the clinician, who constantly sees that a rapidly diminishing blood volume caused by severe haemorrhage will produce symptoms of shock, so that he is often in doubt whether he is dealing with haemorrhage or shock, or a mixture of both. Now, the volume of blood in effective circulation may be diminished in one or more of three ways: first, by gross internal or external haemorrhage; secondly, by escape of plasma or the fluid part of the blood directly into the tissues (as in trauma) or on to the surface (as in burns), or indirectly by the loss of fluid externally by the secretions (sweat) or excretions (cholera and dysentery); and, thirdly, by loss of blood to the effective circulation owing to its stagnation in dilated capillaries. This capillary dilatation might be induced by reflex nervous influence, by local trauma, or by the action of toxins on the capillary walls. The second and third methods would account for shock when unaccom-

panied by haemorrhage. It is indeed impossible to account for the different clinical types of shock without invoking vasodilatation and transudation of fluid. Immediate shock may be the result of an immediate cause, and it is difficult to see the view that this is due to a nervous reflex producing dilatation in some part of the peripheral circulation—in the flaccid muscles, as suggested by Starling. How the reflex may act is well seen in the speed with which the cheek may be mantled by a blush. The importance of the nervous reflex has been minimized by many, yet there is no doubt that strong nervous afferent stimuli will of themselves cause shock. Crile's view that this was due to exhaustion of the vasomotor centre is no longer tenable, but we must assume inhibition or incoordination of this centre to account for the onset of symptoms of immediate shock.

Can the clinician help to decide the vexed question as to the way in which the volume of blood in effective circulation is diminished in secondary or delayed shock? Is it due to loss of fluid into the tissues of the damaged part, as asserted by Blalock; does it depend partly upon a nervous reflex induced by the barrage of nervous impulses ascending from the injured part, as claimed by O'Shaughnessy and Slome; or may it be due to absorption from the injured part of substances which may injure the epithelium of the capillaries and permit transudation of fluid from the peripheral circulation? The clinician must surely answer that the whole truth does not lie with any one of these views. There is no doubt that much fluid and much plasma are lost into the tissues of a traumatized part, but severe shock may occur in cases in which it would be impossible for enough fluid to have escaped to cause serious symptoms; and there is no reason why constant and powerful afferent stimuli from the injured part should not reflexly contribute to shock as they appear to do in cases of immediate shock.

The view that toxins from the breaking down of tissues in the injured part might produce shock was widely held during the last war but gradually lost favour and received little experimental support. Recently, however, H. N. Green obtained a shock-producing substance from fresh voluntary muscle; he found that it was rapidly destroyed in the muscle after death and therefore might easily be missed. Given intravenously, this substance had a powerfully depressant action on the blood pressure. Clinically one can judge little as to the likelihood of shock-producing substances in muscle, but no one who has seen the occasional rapid development of shock following the relief of obstruction of a coil of small bowel will be likely to doubt that toxins absorbed from the small gut may occasionally have a shock-producing effect. How such a toxin may produce shock is a subject for speculation.

It is a matter of common clinical experience that some cases of shock fail to respond to treatment or respond only for a time. The pathological process goes so far that it cannot be reversed. Mere haemorrhage can be rapidly made good by transfusion, but with some cases of severe shock no amount of blood or other fluid infused into the vessels will maintain pressure: either the fluid constantly transudes from the vessels, or the vasomotor centre cannot maintain the pressure in the vessels.

Conclusion

Our clinical scrutiny of the pathology and symptoms of shock leads us to conclude, therefore, that there are several mechanisms which may produce the same result—failure of the peripheral circulation—and this failure may be indicated by several differing clinical pictures.

A fifth edition (1944) of the Orthoptists' Section of the National Register of Medical Auxiliary Services has now been published by the Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1. Orthoptists whose names are included have qualified according to a standard approved by the Board. The Board also maintains registers of physiotherapists, radiographers, dispensing opticians, chiropodists, and speech therapists; and a register of dietitians is being prepared. The Board is anxious that the fullest possible use shall be made of all sections of the Register, and copies of any or all sections will be supplied free to medical practitioners, hospitals, local authorities, etc., on application to the acting secretary.

THOUGHTS ON FOUR YEARS OF WAR SURGERY—1939 TO 1943

BY

General PHILIP H. MITCHINER, C.B.E., T.D.
M.D., M.S., F.R.C.S., D.Ch (Hon)

Surgeon to the King, Surgeon to St Thomas's Hospital

to me that one may now profitably look back and assess the value of the surgical procedures carried out during the four years of war. Enough time has elapsed and casualties have been treated, both overseas and at home, such an assessment to be made of whatever progress has been achieved and to draw conclusions as to the value of the methods adopted. In this respect it is a great pity that surgeons and would-be surgeons had not acquainted themselves with the Official History of the War of 1914-18, the Medical Services and the principles and practice of that period or even troubled to read and digest one or two of the smaller books (Mitchiner and Cowell, 1941, and Slesinger, 1943) epitomizing the essentials of the general work and experience so admirably set forth in the Official History.

It is a great deal of the improvement in the medical service during this war but I cannot help feeling that in spite of the advances in surgical units, more rapid ground and aerial transport, and the more frequent medical broadcasts this progress is not as much as one would like to believe, especially in the prevention of sepsis, for the number of limbless patients from the Middle East and North Africa is by no means small. It would appear, therefore, that the self-congratulation into which some of our "specialist" colleagues have allowed themselves to lapse is almost without justification. There is some failure to understand that while the ultimate aim of all surgery is the restoration of health, the primary aim by which this aim is attained are essentially different in war and in peace. The objective in peacetime surgery is the eradication of disease, in war surgery it is the prevention and limitation of infection.

I propose here to deal seriatim with some of the surgical conditions more commonly seen and the types of wounds and operations and to indicate salient points in the treatment where agreement has been made and where agreement has been reached.

Some Common Surgical Conditions

Septic skin conditions are frequent and by no means yield readily to sulphanilamide powders and ointments. A certain amount of residual dermatitis is seen after the use of sulphonamide drugs.

Minor, major and minor, are—as might be expected—not only seen especially among those whose work in the front, in the trenches, in the field, in the hospitals, in the shops, etc. exposes them to minor injuries of the hands and feet. On the whole, progress of these cases is slow though many crippling results are seen. There is no doubt that the rule that all such cases should be admitted early to hospital—where they receive adequate and early treatment combined with immobilization—is productive of the best results.

Hemorrhoids is often seen in its acute form, but presents no problem. It is well known that 70% of pathological changes are retrocaecal in position, the transition therefore frequently static life to the strenuous physical exertion of the Medical Services probably accounts for the large number of these seen in the first few months.

Varicose veins form a large and important class of case. It must be stressed too strongly that unless pain or discomfort is present, no treatment—other than reassurance of the patient—is called for, while the injection of such cases in the absence of valvular incompetence without previous operation is often productive of injection ulcers due to leakage of the material. *Hemorrhoids* are quite common in recruits and occur at very young ages so that I have no doubt that interference with personal sanitary routine consequent on Army life is a cause of this disease. While injection is excellent in its effect if bleeding alone is present under the stress of Army

life I have no hesitation in advocating operative intervention (excision of the piles) in any case in which prolapse is present irrespective of whether this is reducible by itself or not.

Perforated gastric and duodenal ulcers are also of common occurrence, and where prompt surgery is possible good results usually accrue. It is certainly inadvisable to do more than close the perforation.

Carcinoma of the Stomach and Rectum—The number of cases seen in young men is rather alarming and gives food for reflection.

Hernia cases mainly inguinal, are often seen, and it would appear—judging from Army statistics—that some 10 to 15% of the male population of this country suffer from hernia. Alarming figures have been produced about the recurrence rate after herniotomy. Judging from my own personal experience, fully 50% of these "recurrent" herniae are the result of inadequate surgery at the original operation, in many cases congenital hernia sacs still exist *in toto* while inadequate removal of the sac is also frequently observed. It cannot in my opinion, be stressed too strongly that in a young male with good lower abdominal musculature no operation beyond complete removal of the hernial sac is advisable or necessary, repair operations in these cases will lead to deterioration of muscle and a tendency to recur because the natural barrier to herniation is interfered with. Furthermore, in cases with weak lower abdominal musculature, exercises for the strengthening of these muscles should be carried out under proper supervision for three to four weeks before operation. This procedure undoubtedly lessens the recurrence rate in such cases and makes many—otherwise quite unsuitable for operation—fit to undergo it with a reasonable chance of non-recurrence. Do not operate when for various reasons recurrence is obviously to be expected. Operation in such cases helps neither patient nor surgeon.

Chronic epididymitis of dubious origin is quite frequent in the Forces. It usually affects young males aged 18 to 25, in whom there is often no history of sexual intercourse. Bacteriologically, the condition is not regarded as gonococcal in origin, but in some cases this organism has been obtained from the lesion as have also staphylococci, streptococci, and *B. coli* though in the majority the condition is culturally sterile. Clinically, there may be a thickened nodule usually situated on the lobus minor or part of the epididymis but the whole epididymis may be thickened and smooth. Congestive pain and some tender swelling of the testis are sometimes met with. Very seldom can a hydrocele be detected clinically—a point of some importance in the differential diagnosis. The condition is very generally unilateral only, but now and then the epididymides of both sides are almost simultaneously affected. The treatment is conservative, and the condition is of no immediate importance, except for the danger of misdiagnosis which often results in an unnecessary orchidectomy. The differential diagnosis which apparently causes most misunderstanding is that of neoplasm but the absence of any hydrocele makes one hesitate to diagnose a testicular neoplasm, and in such a case conservative treatment by supporting the testicle is always justifiable. The second alternative diagnosis which may be erroneously made is that of tuberculous epididymitis, but in the chronic condition under discussion there is a smooth feeling epididymal swelling and though the cord as a whole may be thickened there is never nodulation of the vas or of the epididymis while rectal examination will reveal no abnormality in the prostate or vesicula seminalis.

Sciatica—A large number of cases of sciatica many of which come on suddenly after strain or accident seem to be traumatic in origin. All such cases must be treated first by complete rest for 14 days when if pain occurs on leaving bed they should be treated in a plaster of Paris bed for 6 to 8 weeks and operation for the excision of the herniated nucleus pulposus undertaken only in patients feeling pain when they move about after leaving the plaster of Paris bed. Further delay in surgical intervention is deleterious whereas the results of operation are usually most satisfactory, and many of the patients are able to return to full duty.

Operations for Internal Derangement of the Knee—From conversations with many surgeons and medical officers I gather a general impression that the results of operation for this

condition are frequently and rather unexpectedly disappointing, both in the long time such patients remain in hospital after operation and from the fact that apparently only about one-third are restored to full Service duty. A careful investigation into these facts by Hedley Whyte shows that of 1,100-odd patients 50% returned in Category A1, after an average stay in hospital and convalescent depot (for rehabilitation) of from 80 to 100 days, according to whether the treatment was given in a military or an E.M.S. institution. In the remaining 50% down-grading had to be carried out in a large proportion of cases. Thus it appears that results of operation for internal derangement of the knee are statistically better than the general opinion suggests, but it must be remembered that those graded A1 may not have been able to carry out their full duty on return to their unit. Anyway, perfection has obviously not yet been reached. It is for consideration, therefore, whether the complete removal of the meniscus, so generally practised by my orthopaedic colleagues, is not a rather too drastic operation, and whether a return to the removal of the damaged part of the cartilage alone would not be advantageous.

Tonsillectomies and operations on the nasal septum undoubtedly constitute scalps for the operating surgeons, but how often do they make the patient any more fit for full duty in the rough and tumble of Service life?

Broken Hypodermic Needles.—I would offer a word of advice to my medical and dental colleagues on the subject of treatment of broken hypodermic needles within the human body. It must be remembered that operation should be undertaken only after careful radiographs, stereoscopic if possible, have been obtained, and that any operation—whether successful or not—is certain to be followed by a painful scar, disability, and often suppuration, while not more than 1 in 500 of these broken pieces of steel causes subsequent trouble if left alone. It is therefore in most cases inadvisable to attempt any surgical intervention for the removal of a particle of a hypodermic needle left in the tissues, and the deeper this is situated the less advisable is operation.

Treatment of War Wounds

The outstanding problem of this war seems to me to lie in adequate and early surgery of the slightly wounded cases, which, after all, still constitute 60 to 70% of war wounds. It is surely economical and advantageous to the national effort that these men should be fit to return to the fighting line in as short a time as possible. I would suggest, therefore, the revision of our methods in this respect, so that precedence of treatment, with a view to securing early healing and prevention of infection, should be given to these more lightly wounded cases. It is furthermore necessary that they should be adequately dealt with by efficient surgeons as near the battle front as possible, and an early return to the front line ensured by active rehabilitation, mental and physical, in an atmosphere of battle.

In contrast to what was seen in the last war, when a large number of wounds were from bullets, those seen in the present war are mainly lacerated wounds of a severe type, and the mortality from these—as might be expected—is much higher. Indeed, in the bombing casualties of aerial warfare it would appear that some 50% of the patients die either as a result of the actual injury plus blast or very soon after from haemorrhage and shock due to the severity of the wound inflicted.

It follows, therefore, that in the treatment of wounds resuscitation plays an important part. This must be carried out early and consistently by the application of warmth, the giving of hot drinks and morphine, and the transfusion of serum or, better still, whole blood. The Blood Transfusion Service has undoubtedly played a great part in reducing the mortality from wounds of all types. At the same time, however, one cannot help feeling there is a tendency to over-evaluate blood transfusion to the detriment of older and simpler methods of resuscitation and wound treatment. Hot sweet fluids by mouth, warmth, and morphine are simpler methods of combating and preventing shock which are applicable under all conditions and by any first-aid worker or doctor, and, moreover, they frequently suffice to restore a patient without resort to blood transfusion, the injudicious administration of which is not free from risk of fatality.

It cannot be too strongly emphasized, in my opinion, that risk of septic infection from administering blood on the field battle and in the street during an air raid is extremely great and I have no hesitation in saying that blood or serum should not be given intravenously further forward than the advanced dressing station on the field of battle, the sick-bay where it is functioning adequately in a ship, and the first-aid post during an air raid. Moreover, there is, I think, a tendency to give large quantities of blood unnecessarily and wastefully. A general rule, one pint should be administered fairly rapidly in cases of haemorrhage, and a further pint or possibly two by drip method; in the case of shock without haemorrhage, plasma or whole blood should be given by drip method alone and run in rapidly, otherwise the risk of pulmonary oedema is very real.

It has been universally agreed that thorough removal of damaged tissues as soon as possible after the infliction of a wound is essential in securing rapid healing, preventing infection, and ensuring quick return of the patient to health and utility as fighting unit. It is also agreed that excision need only involve a narrow margin (at most 1/4 in. of skin) but that all damaged muscle must be carefully removed until contractile tissue, the vessels of which are spurting and not oozing, is reached. Furthermore, when this treatment has been carried out and adequate drainage ensured from the most dependent part of the wound, no primary suture is to be contemplated.

Notwithstanding, cases in which success has followed primary suture are from time to time reported in the medical journals, no mention is ever made in these articles of the number of cases so treated by the author in which infection, disaster, loss of limb, and even death have resulted. Primary suture of such cases cannot be condemned too strongly; secondary suture can often be carried out with safety in a few days.

These are no new principles to have been learned, though in many cases they have been arrived at after painstaking work on the part of the surgeons and considerable suffering, doubtless, on the part of many patients. All of them emanated from the practice of surgery not only in the war of 1914-18 but in earlier wars. Even the closed-plaster technique, now universally accepted as the best treatment for all types of wounds in the field subsequent on excision, had its devotees and advocates (admittedly few in number) in the war of 1914-18, and even in the Crimean War, though all credit is due to Trueta, who popularized it during the Spanish War.

The dusting of wounds with sulphanilamide (5 to 10 g.) is advisable, both as a first-aid measure prophylactically against septic infection and as a routine after the excision of all wounds. So used, the sulphanilamide is seldom harmful provided that ample fluid intake can be assured to the patient, but it must be remembered that even with the treatment here advised, and more often when packing the wound with a mass of sulphanilamide has been resorted to, severe, even fatal, complications have occurred.

Special Types of Wounds

Abdominal Wounds.—Here early and rapid surgery is essential if life is to be saved, and in spite of advanced surgical centres and rapidity of transport it would appear, from the writings of Gordon-Taylor and conversations with surgeons whom I have met, that the mortality is about 50%, as in the last war, where owing to the static trench warfare such cases were more easily and quickly transported to an operating centre. The mortality from abdomino-thoracic wounds is distressingly high, and indeed is likely so to remain.

Thoracic Wounds.—As in the last war, the surgery of haemothorax from a penetrating wound is conservative, or by aspiration alone where pressure would induce cyanosis and respiratory distress, while in the larger lacerated wounds first-aid and front-line treatment to effect closure is safest and best carried out in the majority of cases by the application of a large and efficient dressing rather than by front-line surgery of a hurried and unsatisfactory type.

Facio-maxillary Wounds.—These should be treated in conjunction with a dentist and a facio-maxillary surgeon; and here the amount of bruising and the extreme disfigurement may suggest that the damage is far more extensive than is really the

ase. Excision must be reduced to a minimum, and mucous membrane should be sutured to skin in every case when the services of a facio-maxillary surgeon are not immediately available. If the wound has disrupted the symphysis menti and detached the tongue, the tendency of this organ to fall back and suffocate the patient must be counteracted by pulling it well forward and, if possible, transfixing the tip with a stitch which should be hooked round the ear, holding the tongue in that position. All such patients should be carried, or should walk, tooping forward, and be instructed to insert the index finger down the throat and press the tongue forward should difficulty in breathing arise. Tracheotomy should never be necessary in these cases.

Peripheral Nerve Injuries complicating Lacerated Wounds.—It is now generally agreed that attempts at primary suture involving extensive dissection of tissues in recent wounds, especially where infection is present, are injudicious, but in cases in which the ends of the nerve are cleanly cut and easily accessible, and suture can be carried out without tension, primary suture should be performed even if there is a risk of infection. The earlier a nerve is sutured after its division the quicker and more complete will be the recovery of function.

Injuries of the central nervous system call for no special comment except that no prolonged search for buried foreign bodies should ever be undertaken in the front line, while drainage of the meningeal cavity is at all costs to be avoided.

Vascular lesions involving the great vessels are as a rule rapidly fatal, but one or two cases of suture of these vessels, and even of the heart itself, have been successful. Here, as in the last war, empyema is a frequent, and sometimes fatal, complication.

Fractures

Both simple and compound fractures are probably greater in number in proportion to wounds than was the case in the last war. The outstanding fact in all fracture cases is the delay in union which is occurring as compared with that war. The official view is that this is due to the severity of the disrupting force and the complexity of the accident causing the injury. I cannot help thinking, however, that the greater and more drastic manipulation of fragments which is taking place in order to secure perfect anatomical position is in some ways responsible for the delay in union, and it is questionable whether such drastic methods of reduction are justified in view of this delay and the functional result ultimately obtained. It cannot be too strongly stressed that in compound fractures the early excision of the soft muscle tissues is of more importance than the meticulous replacing of the bony fragments to obtain perfect alignment. In those cases in which damage to the great vessels of a limb accompanies severe compound fracture with extensive laceration of muscles, it is still best to amputate promptly if the patient's life is to be saved, and this applies especially if, in addition, joints have been laid open into the wound.

In through-and-through joint wounds expectant treatment is often justifiable, but this should be accompanied always by immobilization of the limb and extension applied to keep the bony surfaces of the joint separate. Moreover, a careful watch must be kept for the first signs of clinical effusion occurring in the joint, while aspiration of any appreciable effusion is necessary daily to ensure the free circulation of synovial fluid within the joint cavity.

Amputations have frequently to be carried out, and even in this war it is a sound principle to amputate in the first instance, leaving as long a stump as possible below the joint above the site of amputation. Subsequent amputations should be performed only through the upper third of a leg, the lower third of the thigh, the lower third of the arm and forearm; but one cannot help feeling that Syme's amputation has been abandoned more at the behest of the instrument-maker than at the discretion of surgeons; for one can recall many Syme's amputations performed in the last war which enabled the patient not only to continue in Army service but to march many miles without undue fatigue or to the detriment of the amputation stump. It is essential that after-treatment of an amputation should be carried out and the limb fitted by those accustomed to the work, and it is an excellent thing that all such are now undertaken by

the Ministry of Pensions, whose surgeons further ensure that amputees are taught to use their limbs properly.

Burns

It can be said truthfully that the treatment of burns has returned to chaos. It would appear that the Royal Navy, the Army, the Air Force, and the E.M.S. all have their own special problems, as the conditions under which these burns have to be treated differ considerably; the results obtained from the various methods are difficult to contrast, and it is therefore not easy to assess the value of any treatment except under special conditions. It is probable that the resulting chaos is due very largely to the inability—under war conditions—adequately to clean the burn and its surrounding tissues soon after its infliction. It is also probable that in many cases lack of experience contributes largely to the failure of certain lines of treatment which are successful elsewhere. Be that as it may, undoubtedly much work has to be done and a great deal has to be learned about the treatment of burns.

Generally, it can be laid down that the first-aid treatment of burns, certainly of severe ones, is a life-saving measure, and though the official Army treatment is vaseline or vaseline and a sulphonamide, one cannot help feeling that the method of tanning advocated as a first-aid measure by the Royal Navy has its place in the saving of life in severe burns. Sulphonamides dusted on burns in the early stages are liable, unless fluid is given in large doses, to be followed by severe toxic complications. Intravenous serum transfusion should be started early and be continued for prolonged periods by the drip method in all cases of severe burns, while it is an established fact that early skin-grafting, even in the presence of infection of a mild type, greatly facilitates healing and lessens scarring.

Blast

The results of blast are far more severe than those seen during the last war, and, owing to bombing, many more cases are coming under notice. Much has been written about the effect of this destructive element both on land and as a result of underwater injuries. Many fatalities have occurred, and the damage inflicted is in the nature of extensive haemorrhage and, in some cases, rupture of the lung and intestine. Treatment, except in those cases of hollow viscera or haemorrhage indicating operation, is rest and avoidance of movement as much as circumstances permit. It is far better to move such a patient well back in the early stages than submit him to several subsequent short moves.

Wound Infections

Apart from travelling with an extremely high velocity, fragments of shell and splinters of bomb are smoking hot and often cauterize the flesh at the point of entry, which place may be extremely difficult to detect from its small size and small burned area. Moreover, such projectiles are inclined to cut the clothes cleanly, and the tendency to force clothing material into the tissues is extremely small compared with that seen in the last war. For these reasons, surely infection should be less severe than in previous wars, but this does not mean that it is not to be both expected and counteracted in every wound.

Sulphonamides.—Infection of wounds has been much modified and the terror greatly reduced by the introduction and early use of the sulphonamide group of drugs. It is not suitable in an article of this nature to enter into details of such treatment, particulars of which can be obtained from the Medical Research Council War Memorandum (1943) and the works of Colebrook and other authors. I must, however, sound a note of warning against the excessive and indiscriminate use of these drugs, which are by no means without risk. Many patients show an idiosyncrasy to drugs of this group, while certain organisms react only to certain types of them. It is essential, therefore, that treatment be carried out in close co-operation with a bacteriologist. Moreover, any dosage over 15 g. applied externally may produce toxic and even fatal results, even in cases where the fluid intake can be kept up by both intravenous and oral administration for two to three days subsequent to the use of the sulphonamide. In this respect attention is drawn to the value of the simple test advocated by Fuller (1942), which is accurate enough to serve as a guide that the requisite blood

concentration of sulphonamide has been reached. Remember that the sulphonamides, far from constituting a panacea for all infections, may be actually deleterious and even dangerous, and as a general rule their use should be discontinued promptly in cases which show no constitutional improvement or fall of temperature in 48 hours.

Penicillin.—It seems certain that in its effects against sepsis due to certain organisms penicillin far surpasses all other antiseptics. It is non-toxic to the patient, and one can assert confidently that its future use is likely to be extensive and very successful. Its action is most dramatic on the staphylococcus and gonococcus, and it is not without effect, especially in combination with sulphathiazole, on most streptococci, meningococci, and some types of pneumococci, as well as the clostridia of gas gangrene, *B. tetani*, and anthrax and other Gram-positive bacilli. It has, however, no potency against, and is indeed apparently destroyed by, the Gram-negative bacilli of the *B. coli-typhosus* group. It is obvious from this fact that the drug can be used only in close association with a bacteriologist unless discredit is to ensue. Furthermore, from the surgeon's point of view it would appear that its use will entail a drastic revision of surgery of wounds; for penicillin acts at its best in a puddle of pus, and in cases in which it is applied locally—the most economical and satisfactory way of using it in wound surgery—it seems that drainage will have to be avoided.

Tetanus.—Thanks to the prophylactic and regular use of tetanus toxoid, and the possibly unnecessary prophylactic injection of antitetanus serum in the case of severe wounds—perhaps only unnecessary in those cases where three or more doses of tetanus toxoid have been administered—tetanus is a disease of which we have seen little in this war, and in the few cases which have occurred it has been only of a mild and often non-fatal type.

Gas gangrene has also occurred less frequently and on the whole less virulently than in the last war, possibly because of the nature of the country in which most of the fighting has taken place. To be of prophylactic value, anti-gas-gangrene serum and sulphonamides must be employed immediately after the infliction of the wound; they seem to have little value if employed later and next to no value if the disease is established. It cannot be too strongly emphasized that adequate excision (especially of all damaged muscle) of a wound in the early stages after its infliction is the best prophylactic against all types of this infection. Credit is due to J. D. MacLennan (1943) for his excellent article on the clinical characteristics of the infections resulting from the various anaerobic clostridia and streptococci.

Rehabilitation

Rehabilitation is a new word to many of the profession, who have been all too prone to patch up a case in hospital and take no further interest in its progress or to ascertain whether the patient is fit to return as a working unit in the national effort. The shortage of man-power has directed attention to the necessity for restoring every patient possible to full working capacity in the shortest time. To this end rehabilitation has appeared—indeed, become popularized—and has come to stay. Active rather than passive exercise, mental occupation, and stimulus play an important part in the return of the patient to full work, and it cannot be too strongly emphasized that the psychological outlook of every patient is as important as his physical re-education. The psychiatrists, by-product of the necessities of the war, have come in for much undeserved—and some deserved—criticism, but their value in the war effort is undoubted, and their future as a specialist branch of the profession is assured.

Venereal Disease

A word should be said of the treatment of venereal disease. The introduction of sulphonamides has so simplified both the cure and the time taken to effect it in the case of gonorrhoea that the vast majority of cases of this disease can be treated safely and satisfactorily as out-patients and a cure be assured in a few days.

Syphilis continues to be a problem in regard to treatment, and the large number of cases of jaundice following the administration of arsenical compounds show that none of these drugs in the treatment of this distressing malady; while the

conditions consequent upon war and the movement of the bulk of the population make it difficult to follow up and to administer efficient treatment to many of the infected cases—a fact which must have a deleterious effect on the health of members of the community born and yet to come.

The war has produced a very authentic and connected description of lymphogranuloma inguinale, for which we are indebted to Stammers (1943).

Anaesthesia

I would like to add a word in praise of the anaesthetists, who are doing a magnificent work to assist their surgical colleagues in all parts of the world. Many forms of anaesthesia are practised and advocated, and on the whole the majority are satisfactory in the experience of the surgeons for whom and of the patients to whom they are given.

Conclusions

An endeavour has here been made to assess the value of surgery in the past four years of war and to draw such conclusions as may be possible as to where ground has been gained or possibly lost, in comparison with surgery as practised in the war of 1914–18. It would appear, by and large, that surgical procedure has not altered greatly, though the type of wound has altered somewhat owing to the use of more lethal explosives and missiles.

On the whole it seems that my surgical colleagues have reason to congratulate themselves on the work they are doing, but have no grounds for halting or feeling complacent in this world wide struggle, not yet concluded.

I wish to thank my colleagues on the staffs of many E.M.S., Naval Military, R.A.F., and Allied hospitals, who have received me with much kindness and courtesy on the many occasions on which I have visited them.

NEUROPSYCHIATRY AT A ROYAL AIR FORCE CENTRE

AN ANALYSIS OF 2,000 CASES

BY

S. I. BALLARD, L.R.C.P.&Sed., D.Psych.
Squadron Leader, R.A.F.V.R.

AND

H. G. MILLER, M.D., M.R.C.P.
Flight Lieutenant, R.A.F.V.R.

This centre is situated in a large R.A.F. station and also provides neuropsychiatric out-patient service on a regional basis for R.A.F. and W.A.A.F. personnel from surrounding stations of Technical Training, Flying Training, and Operational Commands, together with the associated R.A.F. hospitals within the area of its regional distribution. The proportion of air-crew cases coming direct from Operational Commands is low, being less than 15% of our series.

Hospital Facilities

Beds are available at the Centre for the observation of cases of psychoneurosis, psychosis, and psychopathic conduct disorder before disposal by return to duty, admission to hospital, or invaliding. Facilities are also available at neighbouring R.A.F. hospitals for in-patient investigation of organic neurological cases, while these hospitals are visited regularly for consultation, as many cases are admitted to them with symptoms which require psychiatric investigation before making a psychotherapeutic approach to their problems. Of such cases, the nervous dyspepsias, and the indefinite headaches vaguely attributed to ear, nose, and throat conditions, are numerous enough to be worthy of special mention.

An adjacent R.A.F. convalescent depot provides a large number of patients with psychoneurotic manifestations, either of a constitutional type or, more often, of a type complicating convalescence from physical injury or disease. In conjunction with the valuable physical methods of rehabilitation employed, psychiatric supervision and psychotherapy of a simple type have proved a valuable factor in shortening the period of incapacity and hastening return to duty.

Recruits Centres

A considerable part of the work is concerned with recruits centres, where the primary problems are those of diagnosis and selection as regards Service trades, the recasting and recategorization of misfits, and the exercise of an advisory function in respect of psychologically adverse aspects of training, together with the more difficult problem of correct disposal. This may be defined as placing the individual in the highest medical category in which he is capable of giving efficient service, and in recommending his employment in a trade in which he is most likely to be of the greatest value. The latter requirements are neither easy to fulfil nor indeed always possible, but nevertheless much can be done in this direction. It is to be emphasized, however, that only cases selected by Unit Medical Officers are referred to the neuropsychiatrist, and nothing in the shape of a routine examination of all cases is undertaken.

Analysis of Case Material

The 2,000 cases here discussed represent the work carried out at this centre in a period of just over twelve months ending in Aug., 1943. They are consecutive cases, and are new ones seen at the first interview. Cases attending on subsequent occasions for investigation or treatment have not been included.

TABLE I.—Analysis of 2,000 New Cases

Diagnosis	No. of Cases
Psychoneurosis	1,366
Organic nervous disease	439
Mental defect	62
Psychosis	45
Malingering	2
Miscellaneous medical conditions	56
No evidence of significant neuropsychiatric disorder	30

TABLE II.—Analysis of 1,366 Cases of Psychoneurosis

Diagnosis	No. of Cases
Affective disorder, including anxiety states, reactive depressions, and fatigue syndromes	739
Hysteria	330
Obsessive—ruminative and compulsive states	7
Psychopathic states	290

TABLE III.—Analysis of 45 Cases of Psychosis

Reaction Type	No. of Cases
Schizophrenic	23
Manic-depressive	11
Paranoid	3
Organic { Toxic-confusional	5
{ Traumatic	2
{ Presenile	1

TABLE IV.—Analysis of 439 Cases of Organic Nervous Disease

Diagnosis	No. of Cases	Diagnosis	No. of Cases
Head injuries: acute	37	Peripheral nerve lesions	7
sequelae	88	Post-encephalitic Parkinsonism	6
Nocturnal enuresis	63	Poliomyelitis: sequelae	5
Epilepsy	39	Cerebral thrombosis	5
Sequelae of meningitis	36	Narcolepsy	4
Migraine	28	Subarachnoid haemorrhage	4
Sciatica	21	Encephalomyelitis	4
Bell's palsy	13	Cerebral tumour	3
Brachial neuritis	11	Adie's syndrome	3
Disseminated sclerosis	10	Other neurological and miscellaneous conditions, including air sickness and non-epileptic loss of consciousness	43
Neurosyphilis	9		

Of the sequelae of meningitis 33 cases followed meningococcal and one pneumococcal meningitis, and two followed benign lymphocytic choriomeningitis; of the four cases of encephalomyelitis, two followed primary vaccination, one

mumps, and one was unassociated with recognized preceding illness. Two of the peripheral nerve lesions (inferior gluteal and partial sciatic syndromes) followed the intramuscular injection of sulphapyridine into the buttock, and were slow to resolve. The cerebral tumours were respectively frontal glioma, parasagittal meningioma, and colloid cyst of the third ventricle. Among the 22 other neurological cases were included cases of subacute combined degeneration, amyotrophic lateral sclerosis, Little's disease, paraplegia from Pott's disease, spinal arachnoiditis, optic atrophy, and occupational cramp.

Discussion

Table IV is self-explanatory. It would seem that few fully developed neurological syndromes now evade the Recruiting Boards; the cases which slip through are those in which diagnosis depends chiefly or entirely upon the history, as in epilepsy and migraine. This applies also to many of the high-grade feeble-minded who may appear normal and plausible enough on superficial examination. Most of the cases of systemic nervous disease occurred in the older age groups, and were referred largely from recruiting centres after only a short period of service. One difficulty in organic diagnosis is the fact that cases are usually referred at a very early stage in their development—not infrequently before the appearance of any unequivocal organic signs. In some cases it is difficult, on the evidence available, to reach the clear-cut decisions as to diagnosis and disposal demanded by Service conditions: this is perhaps particularly so in the case of epilepsy without eye-witness accounts of an attack, where diagnosis may depend on a careful assessment of probabilities.

A lesson learned from the full routine neurological examination of large numbers of cases is that minor organic abnormalities may be found in the complete absence of symptoms or significant aetiological clues.

A notable and apparently increasing tendency is evident in the reference of patients suffering from sciatica with a diagnosis of prolapsed intervertebral disk. Such a diagnosis is sometimes made in cases of first attacks of recent onset without significant signs, a convincing traumatic history, or an adequate trial of conservative treatment, and it may lead to the invaliding of an airman who might, by patient medical treatment, be restored to full effectiveness. In our experience few cases of this type do not respond to rest in bed, and chronic cases are often those in which the exhausted patience of the doctor and the patient has led to premature resumption of activity. The fact that absence of the ankle-jerk may persist for months or years after an attack of sciatica, and that such a finding may be associated with hysterical perpetuation of symptoms, should also be more generally appreciated. Another noteworthy feature among these organic cases is the high incidence of brachial neuritis. The danger of intramuscular injection of sulphapyridine in the neighbourhood of important nerves is also illustrated.

The majority of the cases of mental defect were referred because of hysterical symptoms, frequently bizarre and baffling to the organically minded investigator, or because of general ineffectiveness or petty disciplinary offences. In the assessment and disposal of these cases the executive report on the airman's efficiency and usefulness which is forwarded with every neuropsychiatric case referred is often invaluable.

Predisposition.—A significant past history indicating predisposition was a positive feature in over 80% of 250 unsorted cases of psychological disorder in which routine case records were analysed in retrospect. Significant findings in the history of these cases were neurotic character-traits (70%), manifest psychoneurotic symptoms leading to medical attention in civil life (62%), chronic invalidism (39%), and previous "nervous breakdowns" (28%). There was a positive family history of psychological disorder in 51% of cases, 17% coming from broken homes, while 29% showed a poor civil work record and 15% significant educational backwardness.

Predominance of Affective Disorder.—A striking feature of the 1,366 cases of psychoneurosis is the high proportion diagnostically grouped as "affective disorder" (54% of all psychoneuroses, 37% of all cases seen). In the production of these conditions we would stress the importance of predisposition, and of boredom, monotony, and separation from home, rather than real or anticipated exposure to physical danger.

Recognition of Psychosomatic Illness

Another feature of these cases of psychological disorder is the frequency with which extensive and repeated investigation for the presence of organic disease, and not infrequently lengthy and fruitless courses of treatment directed to ill-defined organic conditions, had been carried out for psychosomatic complaints; the origin of which in personality difficulties rapidly became apparent on the taking of a psychiatric case history. This had occurred more frequently in civilian life than in the Service.

We would particularly stress two points. First, the importance of a personality assessment before carrying out surgical treatment not urgently indicated. The surgery of election for minor disabilities under Service conditions, performed on those severely disposed to neurosis, especially when they are unwilling conscripts, or on the high-grade feeble-minded, is more than usually conducive to hysterical sequelae, and this appears to be particularly frequent when spinal anaesthesia is used. One case of gross hysterical ataxia, unusually resistant to treatment, dated from casual statements overheard under such conditions in the highly suggestible atmosphere of the operating theatre. Indeed, the whole question of what is said to and in front of these patients is extremely important and often neglected. To tell a highly suggestible neurotic that there is a "brain adhesion," "a block in the cerebrospinal fluid," or "a tired heart" is apt to fix his symptoms, in some cases possibly for life, and this type of diagnosis appears to have been made in many of our cases in the complete absence of signs of organic disease, in order to satisfy the demand made by the patient and by the doctor for some physical explanation of his condition.

On the positive side we would stress the importance of psychological preparation for surgery—of a clear, simple, and reassuring statement of what the position is, what it is proposed to do, and what result can be expected. Surgical intervention may be the beginning of years of neurosis, more disabling than the condition which it sets out to relieve: this could often be avoided by explanation and reassurance, which would pay a rich dividend in functional results.

Malingering

The small number of cases of flagrant malingering is noteworthy, but exaggeration of subjective symptoms is relatively common, and is difficult of substantiation in a court of law, whether military or civil, while it is commonly associated with constitutional instability or psychopathy of such degree as to render the individual of little value from the Service point of view. In our experience the genuine, deliberately calculating malingeringer presents a clinical picture of symptoms without signs, ruthless egocentricity with little sense of social responsibility, little evidence of emotional instability, and an absence of recognizable indications of psychoneurosis, psychosis, or intellectual defect. In these qualities such a malingeringer is not far removed from his next of psychopathic kin, the more intelligent criminal of the non-violent type.

In many of our cases of psychopathic conduct disorder a fabricative component has been recognized, and, while the psychopathy has been recorded for future guidance, the man has been returned to duty for executive action. Such cases have therefore been shown under the heading of "psychopathic states" rather than as malingeringers.

Recommendations for Disposal

Of the 2,000 patients 71% were returned to duty with or without change of employment or category, 14% admitted to hospital, and 15% invalided. Table V indicates the comparative disposals of R.A.F. and W.A.A.F. organic and functional cases:

TABLE V.—Comparative Disposals

	R.A.F. (1,765 Cases)		W.A.A.F. (235 Cases)	
	Functional (1,352 Cases)	Organic (413 Cases)	Functional (209 Cases)	Organic (26 Cases)
Duty	74%	75%	42%	46%
Hospitalized	16	12.5	10	18
Invalided	10	12.5	48	36

The considerable difference in invaliding percentages between R.A.F. and W.A.A.F. personnel in both groups is in our opinion principally due to the greater difficulty in adaptation to Service conditions experienced by women, whose cases reveal an appreciably higher degree of constitutional emotional instability and neurotic predisposition. This is shown particularly in such factors as broken homes, unduly strong attachments to home and parents, and previous evidence of lack of persistence and of social adaptation. Many are solitary, shy individuals, living at home, with few external interests, addicted to knitting and sewing, and dependent on maternal decisions. A considerable proportion have never had a civilian job. This group is a particularly unfavourable one, and tends to break down readily under conditions of community regimentation.

The tendency for women to form strong emotional attachments, either hetero- or homo-sexual, is also a potent contributory factor, and the exigencies of the Service—e.g., posting—frequently lead to neurotic conflicts, with much emotional disturbance in the temperamentally unstable, resulting in psychiatric investigation and sometimes in invaliding. A further large group in W.A.A.F. personnel comprises those referred as "problem cases." The majority are psychopathic states of the aggressive group, and of a mild type, more or less antisocial in behaviour, and episodically disturbed in conduct, usually in the face of relatively minor difficulties.

The problem of temperamental instability and psychopathy in the Service is complex, but is more particularly so in the W.A.A.F. because of the lack of appropriate disciplinary measures to deal effectively with cases of conduct disorder in the merely unstable, as opposed to the truly aggressive antisocial psychopath, on whom punishment has but little deterrent effect. This latter group is a small one.

There are, of course, numerous other contributory factors, but those given in broad outline above are the most frequent in occurrence and explain the difference in invaliding rates; for it is useless to return such women to duty, whereas men can and frequently do make a satisfactory adaptation.

Airmen's Convalescent Depot

During the period under review 224 new cases were seen from this depot. Of these, 79% were returned to duty, 16% transferred to hospital, and 5% invalided. This figure does not include 112 cases at A.C.D. which had been seen beforehand by one of us and recommended for admission for treatment.

The new cases fall into two large groups: (1) those admitted as psychosomatic cases; (2) those admitted as medical, surgical, or orthopaedic cases, in which subsequently the psychosomatic component was shown to be of primary importance. The latter group includes psychoneurotic manifestations occurring during convalescence from physical illness or injury.

Every new case is reviewed completely and anew from the neuropsychiatric angle, whether or not the patient has been seen by a neuropsychiatrist elsewhere. This is essential, since in many cases it is necessary to counter previous medical opinions suggesting organic disease, and the patient is more likely to appreciate an alternative point of view if his story has been listened to with patience and attention. Any doubtful point of organic pathology is at once investigated, the authority of the appropriate specialist being freely invoked if necessary. Having cleared the organic ground, a direct approach is made in the form of evaluation of symptoms, with explanation and reassurance couched in the simplest of language, coupled with free suggestion, given with optimism and conviction. This simple form of superficial psychotherapy is reinforced by a system of carefully graduated exercises, games, and physical training. Occupational therapy is fully utilized, and has proved most beneficial and popular. After the first visit the patient is seen once a week by the psychiatrist, who continues to encourage him to persevere with physical exercise, and helps in solving his personal problems.

The process of rehabilitation is much assisted by the general atmosphere of the depot, where the patient sees other badly damaged men being restored to functional efficiency. In his games he develops a team spirit, helped by the fact that all ranks are treated alike. Apart from the physical side, an important factor in promoting recovery, particularly in those who have recently joined, is the relaxation of the Service

atmosphere; thus the airman lives in civilian hotels, and after the day's programme of rehabilitation he is free to go out, untrammelled by sentries, camp gates, and the like, the only restriction being the requirement to return to his billet by 10.30 p.m. Late passes and sleeping-out passes are, however, available in reasonable numbers.

A valuable adjunct to the method of rehabilitation is provided by the attitude of the physical training instructors, who, by their continued enthusiasm and high morale, form models of deportment and zest; and these qualities are reflected to a surprising degree by members of their classes.

In this atmosphere superficial psychotherapy is in many cases sufficient to clear up even chronic psychosomatic symptoms. A certain proportion do not improve because of chronicity, previous firm fixation of symptoms, lack of co-operation, or an obvious motivation in the form of a wish to leave the Service. Severe anxiety states, depressions, and obsessional states do not do well at A.C.D.; they require more prolonged and intensive psychotherapeutic measures, and conditions of life which a Service convalescent depot cannot be expected to provide. From this section of unsuitable cases are drawn those for hospital treatment or for invaliding. The rate for return to duty is somewhat higher than that for the whole series of cases analysed, despite the fact that the A.C.D. cases are of a more severe type.

We are convinced that many patients returned to duty after a period of rehabilitation at A.C.D. would otherwise have been invalided or have remained ineffective for a very prolonged period, and that such results indicate the urgent need for similar facilities in relation to the civilian general hospital. In such circumstances both the patient convalescent from severe illness and the chronic neurotic can be handled under optimum conditions and a partial solution, at any rate, of the out-patient problem be achieved. In our opinion psychiatric facilities are an integral part of such a scheme.

Summary

Two thousand consecutive cases seen at an R.A.F. neuropsychiatric centre are analysed into diagnostic groups, and the organic and psychological cases briefly discussed. Among the points raised are the high incidence of affective disorders and the role of predisposition, the importance of psychological factors in surgical treatment, psychiatric aspects of malingering, and the value of rehabilitation in psychoneurotic cases.

We wish to thank Air Vice-Marshal C. P. Symonds, C.B., Air Commodore H. L. Burton, and Air Commodore R. D. Gillespie for advice in the preparation of this paper, and we are indebted to Group Captain P. H. Young, senior medical officer of the station, for help and encouragement.

SPONTANEOUS RENAL APOPLEXY WITH RESUSCITATION AFTER CARDIAC ARREST

BY

S. L. GOVERNALE

Major, M.C., A.U.S.; Chief of Surgery, Detachment "A"

AND

A. G. RINK

Lieut.; Executive Surgical Officer, Detachment "A"

(General Hospital, U.S. Army)

Very few cases of spontaneous renal apoplexy are to be found in the literature. Two years ago George Crile jun. reported three cases, and at that time a survey of the literature revealed 17 instances. We wish to add one which came to the surgical service of one of us (S. L. G.): It is of additional interest because of the cardiac arrest during operation, which was relieved by an intracardiac transfusion of 300 c.cm. of blood followed by 500 c.cm. of saline solution.

We consider intracardiac or intraventricular transfusion worthy of trial when all other avenues of intravenous infusion are ruled out because of collapse. Such cases may be encountered in collecting stations, casualty wards, or emergency rooms of civilian or military hospitals.

Case Report

In May, 1939, a woman aged 36 was seized with severe abdominal pain in the right upper quadrant while sitting in a cinema. The pain came on suddenly, just after she started to laugh at an amusing episode in the film. She became weak and was taken home by taxi. A medical man was called in. He stated that she had a large tumefaction in the right upper quadrant of the abdomen. The area was rigid. She had vomited on several occasions. Morphine was given and local ice packs were applied.

About 16 hours after the onset of the pain she was examined by one of us and admitted to hospital. The examination disclosed generalized abdominal tenderness and the presence of a large tumour mass in the right side of the abdomen, which extended from the right subcostal region to the iliac fossa. The right rectus and the right lumbar muscles were rigid. Kernig's sign was positive on the right. Her face was pale and there was evidence of "air hunger."

Laboratory examination revealed 2,000,000 red cells, 12,000 white cells, and 50% Hb. The urine contained an occasional hyaline and granular cast, a few red cells, and albumin+. The patient's temperature on admission was 97.6° F., her pulse 120-130, and blood pressure 80/50. After treatment of shock and observing the patient for 14 hours an operation was performed. A right pararectal incision was made, the peritoneal cavity did not contain free fluid. A large dark mass arose from Morrison's fossa and could be seen to extend caudally to the right iliac fossa, thus completely obliterating the right paracolic gutter. The posterior peritoneum was incised and many black clots evacuated. There was slight oozing in the region of the right renal pelvis. The right renal artery was not identified.

At this juncture the anaesthetist announced that the patient had died. The operator (S. L. G.) massaged the heart through the diaphragm and was able to restore and maintain the heart-beat as long as the massage was applied. Nikethamide (coramine) and metrazol were administered intracardially by means of a Pitkin spinal needle. These injections, plus massage, resulted in cardiac activity as manifested by a to-and-fro movement of the visible part of the needle.

Attempts to transfuse blood via the venae comitantes of the brachial artery and saphenous veins were unsuccessful. The situation was critical, and since an entrance to the patient's circulation was established by the Pitkin needle, the Baxter bottle containing the blood for transfusion was attached to this needle. 300 c.cm. of blood was infused by this route, followed by 500 c.cm. of intravenous saline. The patient's condition improved and the heart began to beat again; the wound was packed and closed in layers, and the needle removed.

The patient died 18 hours after operation and 48 hours after the onset of spontaneous renal apoplexy, from a secondary or recurrent right renal haemorrhage.

Conclusion

The apoplexy was the result of a long-standing malignant hypertensive cardio-renal disease, as brought out by the patient's history, the episode narrated above, and the post-mortem findings of contracted kidneys, nephrosis, and atheromatous degeneration of the aorta and renal arteries.

Summary

A case of spontaneous renal apoplexy due to malignant hypertensive cardio-renal disease has been presented.

The patient's heart stopped during operation.

Cardiac resuscitation was accomplished by cardiac massage, intracardiac injection of stimulants, and intraventricular infusion of blood and saline.

Life was restored for a period of 18 hours after the operation.

Death ensued from secondary or recurrent right renal haemorrhage.

Perusal of the literature does not disclose any previous reported case of intracardiac or intraventricular infusion.

Relapsing fever is one of the infections that follow in the path of war. For example, it is estimated that in the year after the 1914-18 war over a million and a half persons in European Russia were affected with this disease. In the big epidemics the louse has been the vector of the infecting spirochaete, first observed by Obermeier in the blood of a patient in 1873. Various species of ornithodoros ticks are known to transmit the disease in many parts of the world. Among normal reservoirs of the infection are several species of rodents, foxes, dogs, and monkeys. Relapsing fever can be satisfactorily treated with arsenic, but F. R. Heilman and W. E. Herrell (*Proc. Mayo Clin.*, 1943, 18, 457) have demonstrated experimentally in mice that the disease can be brought under control with penicillin.

GONORRHOEA IN NORTH AFRICA AND THE
CENTRAL MEDITERRANEAN

BY

DOUGLAS J. CAMPBELL, F.R.C.P.Ed., D.P.H.,

Lieut.-Col., R.A.M.C.; Adviser in Venereology, A.F.H.Q., B.N.A.F.

During recent years the lay public, and even members of the medical profession, have come to look upon gonorrhoea as a condition in which "one just takes some tablets for a few days" and all is well. The danger of such complacency has become increasingly obvious as the campaign has progressed through North Africa into the Latin countries.

While the Army was situated in Algeria and Tunisia the response to chemotherapy ran a course similar to that experienced in the United Kingdom, and failures were usually attributable to irregularity of the treatment, insufficient fluid intake through shortage of drinking-water in very hot conditions, and the hardships of battle resulting in delay in starting treatment. In the last category metastatic complications, such as gonococcal arthritis, were common. Throughout the first months of the campaign sulphapyridine was the drug in general use, administered as a course of 20 to 30 g. in 5 days. Towards the end of the North African phase sulphathiazole, 10 g. in 2 days, was introduced. This was given in forward medical units, so far as was possible, to obviate evacuation. While the response to this form of therapy was not as good as the 90% claimed in the United Kingdom, the 70 to 75% satisfactory results materially conserved man-power and hospital accommodation.

A very different picture presented itself when the campaigns in Sicily and Italy began. Forward treatment of gonorrhoea failed almost completely, and as at first the venereal diseases expansions were still with general hospitals in North Africa, these unsuccessful cases had to be evacuated, and filled the beds of the expansions, which were thus retarded in their movement forward.

A well-staffed and experienced V.D. treatment centre opened in Sicily and, in conjunction with units of field ambulances, endeavoured to stop the need for evacuation to general hospitals. It was immediately evident that short courses of chemotherapy were useless. Less than 25% were responding, and of these a large proportion relapsed on the way back to rejoin their units. Dosage was increased to 25 to 30 g. of sulphathiazole or sulphapyridine in 4 to 5 days, there being apparently little to choose between the drugs. Second courses were necessary in 70 to 80% of cases after 5 to 7 days' irrigation treatment, and as the disease progressed, with lengthening lines of evacuation, more chemotherapy was given, till large numbers of men reached the main V.D. units still showing gonococci in their discharges after receiving as much as 130 g. of various sulphonamides.

In these early days there was some irregularity in the administration of the tablets, but even when this was rectified the same dismal picture of failure continued. The economic conditions in Sicily and Italy which drove women to prostitute themselves for food and chocolate constituted a menace never encountered by our troops before, and the incidence of venereal diseases increased.

As the campaign has progressed northwards in Italy and expert venereal diseases treatment units have moved forward there has been a slight improvement in the picture, but considerably less than 50% of acute gonorrhoea cases respond to an initial course of 25 to 30 g. of sulphathiazole, and relapses are common. Irrigations for the succeeding 5 to 7 days, followed by a second course of sulphapyridine or sulphadiazine, have proved successful in a few cases, but resort to pyrexial therapy by means of intravenous T.A.B. vaccine during this second course of chemotherapy has become almost a necessity. Some success has followed the use of the standard Army gonococcal vaccine.

Gonorrhoea has become a disease requiring a long stay in hospital. Clinically there is a profuse urethral discharge, containing large numbers of gonococci, persisting for many weeks despite the treatment described. Involvement of the posterior urethra occurs early, with considerable incidence of prostatitis

and epididymitis. Epididymitis often occurs when the patient has been in hospital for several weeks under optimum conditions of rest and treatment, and is usually severe. Metastatic conditions such as gonococcal arthritis and iritis are rare. It has been freely suggested that we have met a sulphonamide-resistant gonococcus, due to inadequate treatment of the civilian women, but the shortage of the drugs in Sicily and Italy and the complete lack of treatment of infected civilians over a long period make this idea somewhat unacceptable. The restoration of adequate civilian treatment under the auspices of A.M.G. is progressing rapidly, but it is too early to evaluate results. Rather does it appear that the gonococcus now encountered is a non-reactor to chemotherapy and, further, that it does not stimulate natural antibody responses in the victim. Venereologists with wide experience in the United Kingdom, North Africa, and the Middle East are working together now, and none have previously met similar conditions. Our American colleagues have found the same conditions among their troops, and have had to enlist penicillin as alternative therapy, with considerable initial success. If throughout Europe similar difficulties are to be met in future campaigns, gonorrhoea will be an immense scourge, with resultant strain on medical personnel, hospital accommodation, and man-power. There is no longer reason for complacency.

Summary

Since the invasion of the Latin countries gonorrhoea has proved intractable to the former accepted methods of treatment by chemotherapy.

Treatment must be given regularly and prescribed with ingenuity. Adjuvant methods are necessary in a high percentage of cases.

Experienced venereologists and special treatment orderlies are required in greater numbers than before.

Every endeavour to prevent infection must be made.

Medical Memoranda

Fixation of Tissues from Cases of Malaria

It is common knowledge among pathologists that formalin reacts with lysed blood to produce a dark-brown deposit, and that this occurs both with blood lysed before death (e.g., in an extravasation) and with the intravascular blood which soon after death begins to undergo progressive lysis. This formalin blood deposit unfortunately closely resembles the pigment produced in malaria, and it is thus important, as Lignac (1924) warned, to avoid the use of formalin as a sole fixative for malarial tissues.

Barrett (1944) has recently shown that formalin deposit can be easily removed from sections by immersion for two hours in picric alcohol, and hope was aroused that this might, after all, allow the use of formalin in cases of malaria. To test the effect of picric alcohol on malarial pigment, sections of various viscera (fixed in 95% alcohol and in Zenker's fluid) were treated for one and three-quarter hours; the malarial pigment was almost completely dissolved away. Thus treatment with picric alcohol does not differentiate between malarial pigment and formalin deposit. (Melanin, a possible source of confusion was found in a section of a cerebral metastasis from a melanoma of skin to be apparently unaffected by picric alcohol.)

Formalin is in general not a satisfactory fixative by itself for tissues that are to be embedded in paraffin (Mallory, 1938) but it has one advantage that makes it of particular value to those interested in malaria: it is less lytic towards the fragile post-mortem erythrocyte than is any other common fixative. This property is utilized, formalin deposit largely prevented, and the tissues rendered suitable for paraffin embedding by the following procedure:

Primary fixation is carried out in formalin (10 parts with 90 of water) for 3 to 6 hours (or in formal sublimite if the tissues be less than 6 hours dead), followed by direct transfer to 5% aqueous mercuric chloride, in which fixation is continued for 5 to 20 days (Lendrum, 1941).

This method, which is the ideal routine fixative for human post-mortem material, is suggested for malarial tissues because of the minimal lysis and the clarity of the microscopical picture; but, since there is still a slight risk of deposit, it is essential that tissues from suspected malaria should also be fixed in formalin-free fluids. The two methods of this kind commonly used in the past were fixation in 90% alcohol (ethanol) or in Zenker's fluid. Both of these unfortunately cause lysis of

erythrocytes in post-mortem human material, although with Zenker's fluid this can be partially avoided by omitting the acetic acid.

The following method is suggested as the best formalin-free fixation for human malarial tissue:

Fix in an aqueous solution of 2.5% potassium bichromate and 5% mercuric chloride for about 6 hours, and then transfer the tissues directly to aqueous 5% mercuric chloride; in this, fixation continues without the danger of spoiling the common methods of staining, as may result from the prolonged action of bichromate.

This method gives the minimum of lysis of erythrocytes other than by the use of formalin, preserves the malarial pigment, and of course avoids the fallacy of formalin deposit.

Obstructed Labour with Complicated Presentation and Exomphalos

The following case, which was treated in the London Mission Hospital, Neyoor, Travancore, South India, may be of interest.

CLINICAL HISTORY

An Indian Christian woman aged 23 was admitted to hospital on Nov. 25, 1942. She was a multipara, in labour. She had previously had two normal full-term deliveries, and one child was living. Labour pains had begun 24 days earlier, in the evening of Nov. 22, after spontaneous rupture of the membranes.

On examination at 11.30 a.m. on Nov. 25 her condition was only fair—temperature 100.6°, pulse 96—and she showed signs of exhaustion. The uterus was contracting strongly about every three minutes. The organ was rounded in shape, with the fundus lower than usual. It was difficult to make out the position of the foetus, but it was thought it might be transverse. Vaginal examination was made by the Indian doctor (many such examinations had been done by the barber—"midwife" with no aseptic precautions), who reported that there was full dilatation and the presenting part was a foot with either the head or a buttock, and high up. I then examined the patient and found a vertex presentation with a foot prolapsed on the left side.

In view of the patient's general condition it was decided to deliver her at once, and chloroform anaesthesia was administered. Podalic version was performed with difficulty, and in feeling for the second leg my hand came in contact with soft material, which felt like intestine or membrane. Although version was performed, the baby could not be born beyond the buttocks. The abdomen was to the mother's left, and coils of intestine could now be seen. There was no proper cord formation, but the umbilical vessels could be seen and felt. They were divided close to the child's body, which was then delivered without difficulty. The placenta and membranes followed almost at once. There was no undue bleeding. The patient's condition was no worse, and 1 c.cm. of ergotamine was given intramuscularly. That evening her temperature was 102.6°, pulse 98. Sulphanilamide 1 g. four-hourly was started, and 12 doses were given. She made an uneventful recovery, and was discharged well on Dec. 1, six days after admission, at her own request.

The baby was a full-term male and weighed 64 lb. (a normal weight for a South Indian baby). The head was microcephalic, and deeply grooved on the left side where the leg had lain alongside it. There was a large exomphalos, with an opening in the abdominal wall 3 in. in diameter. Parts of the intestines, the liver, and spleen were prolapsed, and the heart also was lying outside the chest wall, enclosed in the pericardium. This was beating at a rate of 60 a minute. The child started to gasp as soon as it was born, at a rate of about 6 a minute. It lived altogether three-quarters of an hour, the respiration and heart rate gradually becoming slower.

Placenta, Membranes, and Cord.—The placenta was large, diffuse, and thinner than normal. The chorion was normal. The amnion was adherent to the thin wall of the sac of the exomphalos. In this the umbilical vessels could be seen running separately to and from the placenta. They were slightly tortuous, but the distance from the placenta to the edge of the abdominal wall was not more than 6 in. There was no cord formation at all. It was unfortunate that in order to effect delivery the vessels had to be divided. The cut end of the umbilical vein could be seen entering the body on the lower surface of the liver, but the points of emergence of the umbilical arteries could not be seen.

COMMENT

In this case of obstructed labour delay appeared to be due to the absence of formation of an umbilical cord, and to the shortness of the vessels which ran to and from the placenta in the wall of the exomphalos. A foot had prolapsed, making a complicated vertex presentation. Delivery was effected by podalic version and division of the umbilical vessels. In spite of extreme exomphalos and moderate microcephaly the "monster" lived for three-quarters of an hour.

Reviews

RESPIRATORY DISEASES

Diseases of the Chest. By Robert Coope, M.D., F.R.C.P. (Pp 524; Illustrated, 25s.) Edinburgh: E. and S. Livingstone, 1944.

In his preface to this book Dr. Coope states that it is an essay in medical education, and it certainly represents a departure from the standard modern technique of medical writing. The work is indeed an essay on the respiratory diseases rather than a textbook, and it is not intended to be a manual of reference. The author has deliberately subordinated the facts to the broad principles, and he has added a wealth of practical advice which is not usually found in standard medical works. In many ways this volume is more reminiscent of the wise, leisurely publications of fifty years ago. Occasionally his enthusiasm for giving advice leads the author to underestimate the common sense of his disciples: for instance, the comments upon the type of clergyman who should be allowed to visit a patient with pneumonia might well have been omitted. But, on the whole, this book succeeds in teaching a sense of proportion which is not to be found elsewhere.

The chapters on clinical examination and physical signs are particularly excellent and should be read by all students. The signs which are of real practical importance are carefully described, and the statement that many of the so-called classical signs "might now be considered of interest only to medical historians" will be accepted readily by clinicians, but perhaps less eagerly by those who are examiners. Unlike many writers on this subject Dr. Coope is free from idiosyncrasies, and there is nothing to bewilder the learner in his account of physical signs, while there is much that will clarify his ideas. The section on tuberculosis is fairly typical of the general method of approach to individual diseases. It is distinctly sketchy as regards the facts, but it lays down the broad principles of treatment with sound sense and human understanding. Other books may give more about the treatment of the disease, but this one will teach the student how to treat his patient.

Insistence upon fundamental principles has led to a certain light-heartedness with regard to detail, and there are some small inaccuracies which require correction: for example, the anatomy leaves much to be desired, and, again, the student reading about lung abscess would gain the impression that an empyema is a more common complication than an adhesive pleurisy. But to lay undue stress upon these small points would be unfair to the work as a whole, because the facts can be obtained from other sources, whereas this book teaches many valuable things that cannot be learnt from encyclopaedias. In fact this volume is to be commended to all students; they will find it easy to read and will not fail to profit from its wisdom.

THE U.S. DISPENSATORY

The Dispensatory of the United States of America. By H. C. Wood jun., M.D., and Arthur Osol, Ph.D., assisted by H. W. Younken, Sc.D., and J. Gershenfeld, D.Sc. 23rd edition. (Pp. 1,831. £5 5s.) London: J. B. Lippincott, 1943.

The *United States Dispensatory* has now reached its 23rd edition. It is a useful reference book, divided into three parts. In Part I are found drugs which are official in *U.S.P. XII*, the *National Formulary* (7th edition), and the *B.P.* of 1932 with its addenda. The method of dealing with each drug is very similar to that followed in the *British Pharmaceutical Codex*; there is a description of the drug, with details of methods of standardization and a short account of action and uses. Part II deals in a similar manner with drugs which are not official. The compilers of the *Dispensatory* have solved the problem of the very large number of drugs which they might describe by restricting severely their choice of unofficial drugs. Thus, while they take 1,237 pages to discuss official drugs, they confine themselves to 348 on unofficial drugs. The book would be more valuable if this proportion were reversed. Part III is concerned with processes and reagents and similar details referred to in the *United States Pharmacopoeia* or the *National Formulary*.

It is to be feared that the book in its present form loses much of its usefulness. Details of official drugs are available in many books. Details of unofficial drugs are harder to find, and the reduction of the space allotted to them to so small a proportion of the book seems a pity. The other serious drawback from the point of view of British readers is that the original papers referred to are throughout American. There are very few references to British papers and still fewer to Continental ones.

The book is well printed and easy to read, and is probably as satisfactory as such works can be expected to be in these days when there is so much material to be considered for inclusion. It is inevitable that much is included of little interest, and much is omitted which some would like to see there.

THE SUBNORMAL GIRL

The Subnormal Adolescent Girl. By Theodora M. Abel and Elaine F. Kinder. (Pp. 215. 52 50 or 16s. 6d.) New York: Columbia University Press; London: Oxford University Press

This is an excellent and comprehensive study of the subnormal girl of from 10 to 19—the period when problems of adjustment are most difficult for the normal and doubly so for the subnormal. The authors justly point out that there is no interruption in the series from the imbecile to the normally endowed, and consequently the level at which the State can legally take control is an arbitrary one, and there must always be a large number who must remain in the community for better or for worse. It is becoming more and more evident that the certifiable group is almost less of a problem than the dullards. The trouble with the subnormal is that her rigidity makes it so difficult for her to adjust to unexpected situations, and the unreliability of her behaviour results in most unexpected and inappropriate actions.

The subnormal girl is studied in her home, at school and in industry, and in the institution, and cases are quoted to illustrate how these children behave. Such behaviour is by no means always bad, and in favourable circumstances these girls may make good and even come to earn good wages. But even when it occurs this successful adjustment is only achieved at a price, for dullards need prolonged and careful training and much patience and perseverance. When we come to the seriously maladjusted girl we find a record of delinquencies, unwanted pregnancies, and disease which costs the community dear and often militates against the interests of the patient's normal sisters. In a final chapter the origins of abnormality are discussed, and it is admirably argued that since there is no one simple cause for this misfortune there can be no single simple remedy. Sterilization, social betterment, education, and the like may all have their uses, but much research is still needed before a real understanding of the problem and a constructive solution can be reached. A valuable bibliography is appended. This book can be thoroughly recommended to all those interested in medicine, psychiatry, education, and sociology.

Notes on Books

Industrial Nursing: its Aims and Practice, by A. B. Dowson-Veriskoff, is published by Edward Arnold and Co. at 5s. It is an excellent little book, full of information suited to industrial nurses, both those who have the added weight of a doctor's knowledge and authority to support them, and those who have to work without his backing. In the chapter on training it is admitted that the ideal scheme for the training of industrial nurses has yet to be worked out. The one-year courses so far arranged are necessarily expensive, while the three-months and six-weeks courses sponsored by the Ministry of Labour are far too short. Among the ten chapters of which the book consists we find detailed information on the scope and conditions of service of the industrial nurse, on the running of a health department, and on industrial emergencies and routine treatments. The environmental hygiene and the personal hygiene of industrial workers are discussed in other chapters, and there is a detailed chapter on record-keeping, illustrated by numerous sample records. The final chapter discusses co-operation with organizations inside and outside the factory.

Prof. F. J. BROWNE's well-known textbook *Antenatal and Postnatal Care*, first published in 1935, has now reached a fifth edition (J. and A. Churchill; 24s.). The text has been thoroughly revised, and though less than two years have passed since the fourth edition appeared, many changes have been found necessary. There is a new

chapter on the Rh factor and erythroblastosis. An account is given of recent work on diet and pregnancy, especially on its possible effect in preventing various diseases and accidents of pregnancy; and after a critical evaluation of the Toronto experiment and of that carried out in London by the People's League of Health the author writes: "It is impossible after reviewing all the literature on the relation of diet to the disorders of pregnancy to do other than conclude that, while much careful work has been done, many more large-scale, carefully planned, and statistically controlled experiments are necessary before final decisions can be reached."

The Chemistry of Synthetic Substances, by Dr. EMIL DREHER (Philosophical Library Inc., 15, East 40th Street, New York; \$3.00) is a dissertation on a series of substances of unusually high molecular weight and on their production by the chemical coupling of smaller molecular units. Such substances include rubber, plastics, enamels, paints, and other materials which are finding an increasing economic employment, some as substitutes for the products of Nature, others for their possession of special qualities not previously available. The discussion shows how the properties of these products vary according to the chemical nature of the units from which they are built and according to the kind of reaction by which the units become linked. It is a useful summary of the work that has been accomplished in this field.

A third edition of Dr. EVELYN E. HEWER's *Textbook of Histology for Medical Students*, which first appeared in 1937, has now been published, three years after the second edition of 1941. This is good evidence of the continued popularity of the work, and of the demand for a student's book which provides all the more essential facts of human histology without these being obscured by the inclusion of unimportant structural details. A considerable number of excellent low-power photomicrographs have been added; also valuable notes bearing upon the physiological changes which normally take place during processes of activity and return to a resting condition, and of the changes in the life-history of a cell from its formation, through maturity to senescence, to its final degeneration and absorption. Little need be said in the way of constructive criticism. One would like to see an improved technique in the original drawings of some of the high-power magnifications, and in the drawings for reproduction of some illustrations derived from other sources; also a fuller account from the histological standpoint in the description of the sense organs is desirable. The work as a whole may be commended for the use of medical students as a clearly written textbook by an experienced teacher. It is published by Heinemann at 17s. 6d.

Preparations and Appliances

STERILE SULPHANILAMIDE FOR LOCAL USE

Sulphonamide powders for local application to wounds, burns, etc., should be absolutely sterile, and their sterilization in small amounts by users is troublesome. Unless the powder is initially quite 'dry' and temperature accurately controlled, caking may occur, and discoloration is also common. Boots Pure Drug Company Ltd. have now produced a sterile-sulphanilamide for local application. This is a free-flowing crystalline powder with no added ingredient, and is supplied in 15-g. bottles and in 5-g. sifter envelopes. The latter have three coverings of different colours, the innermost of which should be removed with sterile forceps; if the edges are then pressed together at marked points the powder can be shaken from it.

TETANUS ANTITOXIN

Recent Ministry of Health recommendations indicate 3,000 international units of tetanus antitoxin as the minimum prophylactic dose. Burroughs Wellcome and Co. announce their intention of discontinuing the supply of the 1,000-unit packing of "Wellcome" brand refined tetanus antitoxin globulins. As a further safeguard against the use of inadequate prophylactic dosage, multiple-dose packings containing 1,000 units per c.cm. are also to be discontinued. The suppliers recommend that existing stocks of these packings should be used in accordance with the new dosage.

DRIED EXTRACT OF ROSE HIPS

Messrs. A. Wander Ltd. have prepared "Hipexa" tablets containing dried extract of rose hips and estimated to have not less than 7 mg. each of natural vitamin C. The dose recommended is 1 or 2 tablets after each meal, so that a total of 20 to 40 mg. vitamin C per diem would be obtained in this way. It is probable that the present wartime diet at its worst contains as little as 20 mg., and at its best perhaps 60 mg., a day. Probably some individuals would benefit by additional vitamin C in tablet form in the winter months when the amount in the diet is at its lowest. Evidence is accumulating that the amount of vitamin C in the diet influences the tensile strength of scar tissue formed in repairing wounds, so vitamin C tablets may suitably be prescribed for civilians with injuries.

PHENIODOL B.D.H.

A Cholecystographic Agent for Oral Use

Pheniodol, when given orally, is concentrated in the gall-bladder as effectively as is iodophthalein (T.I.P.) when given intravenously. A most convenient method of administering Pheniodol is in the form of Pheniodol Meal B.D.H., a specially-prepared powder readily miscible with water to form a smooth suspension which is easily taken by the patient.

By the use of Pheniodol Meal B.D.H. the incidence of nausea, vomiting and diarrhoea is reduced to a minimum.

Details of dosage and other relevant information will be gladly supplied on request.

THE PLANNERS OF MEDICINE

PEP, which as most readers by now know stands for "Political and Economic Planning," has been quick off the mark to describe and discuss the White Paper on a National Health Service and the reactions of the medical profession to the paper. In 1937 the same organization produced what has with justice been called a "valuable and mainly factual report" on the existing medical services. In its present anonymous publication it comes out as an ardent advocate of the measures for a National Health Service proposed in the Government's White Paper, and in perusing the document the reader becomes increasingly aware of the significance of the words "Political and Economic Planning." The NHI Scheme, it states, is out of date and "must be replaced," the wartime reorganization of the hospital system "must be consolidated," the Government "must" see that "no individual is obliged to pay a fee" and "must solve the problem of the geographical maldistribution of medical resources," the new Joint Board "must take their planning functions seriously," "the Government is right in insisting that doctors in Health Centres must be remunerated by salary or some similar alternative excluding competition," "a hospital participating in the service . . . will have to conform and it will have to submit to inspection." The imperative words we have italicized show clearly enough without further argument the attitude of PEP to the White Paper, and more especially to the medical profession. The dictatorial stress throughout this ably written document rouses uneasy feelings in a profession which by the nature of its work knows full well the value of a second opinion. It may not always be fair to judge a man by the company he keeps, but when the reader looks at the kind of organizations which also join with PEP in its enthusiastic acceptance of the Government's scheme—demurring only because it does not go far enough—he may get some enlightenment on the meaning of the word "political" in PEP. For example, the Communist Party has recently published its views in a pamphlet entitled "Good Health for All," and on page 2 makes this statement: "The Government's proposals have been published after a very great deal of pressure from the Labour and Communist Parties, Co-operative Organizations and Trade Unions, and health workers' organizations, such as the Socialist Medical Association." Of hospitals the Communist pamphlet writes: "Control will be in the hands of the State and the Local Authorities . . . standards will be laid down. The inspectors will judge whether these are observed. If not, the offending hospital will receive no money from the Government." At the same time as this pamphlet was published the Socialist Medical Association

issued a press notice with this statement: "The Socialist Medical Association warmly welcomes the White Paper on a National Health Service as a step towards a socialized health service and part of a general programme of social security. The Government is urged to introduce the necessary legislation at an early date. All doctors should be employed by the Joint Health Authority of the area in which they work."

The Ministry of Health may well regard the Communist Party and the Socialist Medical Association as strange bed fellows, but we believe we shall be doing a disservice to the cause we have in common with the Ministry—namely, the provision of a first class and comprehensive medical service to the country—if we do not give expression to the grave disquiet felt by the majority of medical men who are aware of the need for reform and are genuinely anxious to promote it. At the risk of distorting the position by summarizing it briefly, we would say this fear is for the loss of professional freedom and the recasting of medical services according to political dictate. When a project has the blessing of the Communist Party a liberal profession may well feel apprehensive about the future. The Council of the BMA has already publicly voiced its fears of political influence in medical matters, and as each week passes it becomes clearer just what the political influence is. The present PEP broadsheet gives the reasons for these fears in admirable language.

"Inflexible and pettifogging lay control of doctors out of date methods of appointing and promoting hospital medical staffs, narrow-mindedness and lack of imagination are still far too prevalent among local health authorities. The doctors practising in municipal hospitals are still usually denied the full measure of freedom in their professional work which is the rule in voluntary hospitals, chiefly because local authorities like one man—in this case the medical superintendent—to be clearly responsible for all that happens in each of their institutions whether hospitals, workhouses, or schools. Local authorities still commonly expect their doctors to seek their councils' permission before publishing papers even of a purely medical character, and they do not often invite expert technical advice from practising doctors or other health workers."

"Similarly the Ministry of Health has too often allowed the non health functions which it inherited from the Local Government Board to overshadow its public health duties, it has too frequently combined a meticulous attention to details with a disheartening disregard for fundamentals, in many respects, until recently, it has tended too easily to forget even the outside expert advice which it invited and to shelve proposals for reform, the smugness of many of its pre-war reports on such matters as malnutrition and the health of children still rankles. Too many Ministers have been more interested in party politics than in the nation's health or in the welfare of doctors, nurses and other health workers. Both the Ministry and local authorities not to mention the Treasury, have given too little thought to another of Newsholme's principles—that 'health is worth whatever expenditure is efficiently incurred in its maintenance or to secure its return'."

In citing the Assistance Board as possibly a model form of organization "for some at least of the medical services," the broadsheet goes on to explain that the success of the Board is largely due to the fact that its members are drawn from outside the Civil Service, that they hold office only for limited periods, and that they give only part of their time to the Board's work. PEP observes that the Ministry of Health is largely to blame for the suspicion with which the doctors of the country regard it. Again we will allow PEP to give in its own words the reasons for the

profession's rooted dislike and distrust of the influence of politics in medicine :

"Unfortunately the only real safeguard is the frame of mind of the Minister and his chief officers, which in the last analysis is bound up with politics. No form of consultative machinery can oblige a Minister or a Government to seek and follow expert advice if they are indifferent to 'long-term planning.' The White Paper indicates a change of heart at the Ministry of Health. Doctors will do well to recognize it."

This change of heart has not escaped the attention of the medical profession. But if the change is an enlargement to the left the prognosis is serious. The above quotations from the PEP broadsheet clearly explain why the majority of doctors in the country are afraid of the introduction of politics into medicine. The real objection is not to the party politics of right, left, or centre. If any political party were to introduce a measure of reform that had the support of the majority of doctors then it would be a matter of indifference to the profession whether it was the Labour, the Liberal, or the Conservative Party. Politics are, however, inseparable from both central and local government. A Minister of Health, as we know, is as likely to form his policy on the pasteurization of milk on political grounds as he is on the grounds of the safety of the public health. We even fear that the views of a medical M.P. on such a matter may be as much influenced by the particular interests of his constituents as by the scientific truth of the situation. We know, too, that party politics play just as baleful an influence in local government and in guiding the decisions of local authorities on health matters. What is more, local authorities have been known to judge a medical man's fitness or unfitness to hold a medical post on the ground of his political beliefs. Some recent critics—and these include some doctors—have had the effrontery, in order to gain their own political ends, to accuse the medical profession of being ignorant of the society in which they are living, of having no social sense, of taking no part in the life of the community at large, of being disinterested in "positive health"—a term incidentally coined by one of the most able spokesmen the B.M.A. has ever had. Enemies of the medical profession eagerly seize upon these parrot cries and are at no pains to discover the facts. To take one single example—and we take it because of its supreme importance for the public health—we may cite the activities of the B.M.A. in the field of nutrition. Both the public and the profession need to be reminded that when the Ministry of Health between the two wars appointed a Committee on Nutrition the report never saw daylight—presumably because the contents of the report were politically unpalatable. In 1933 the B.M.A. set up a Nutrition Committee, and made its report available to the public in printed form in the same year. There were political implications in this document, and as one may fairly assume that the majority of the members of the Council at that time did not belong to the Labour Party the public might profitably draw a lesson from this incident. When the Council discussed the report it was not blind to its political implications, but it decided that it was concerned with one issue only, and that was the medical one. The publication of the B.M.A. report did more than anything else in between the two wars to rouse

public opinion on nutrition. In between the two wars a the B.M.A. started a campaign through advertisements the Press on such public health issues as the pasteurization of milk. The publication of its report on physioeducation was yet one more sign of its profound awareness of the socio-medical obligations of the profession. This is what we mean by professional freedom, a freedom publicly to advocate measures of health undeterred by the political considerations that have always hampered the medical man working under the control of central and local government and depending on them for his livelihood.

These remarks are relevant to the PEP broadsheet "Practising doctors," it is stated, "generally are far too isolated from public life. . . ." But PEP then advocates a line of development of policy which will exclude doctors from full participation in public life, as in fact Civil Servants are so excluded. Both PEP and the *Times* leader writer¹ quote with approval the late Sir Arthur Newsholme's saying: "Skilled medical work cannot be controlled by laymen, but in all business arrangements a representative lay power must be supreme." Medical men are not seeking to be supreme in "business" arrangements but they want to secure that "business" supremacy does not interfere with professional freedom. Recently, yielding to pressure, the L.C.C. removed its ban upon the publication of scientific articles without previous censorship, but at the same time so altered the wording of its standing orders as to make it clear that it would not allow the publication of criticism of administration and organization of services without censorship. Throughout the PEP broadsheet the writer has the honesty to admit the contradictions of fact which are stubbornly in the way of the doctrinaire theory to which he is attached. On the one hand he wishes to see the profession put under complete control, and on the other admits that chiefly by combining in the B.M.A. medical men have succeeded in securing "an appropriate measure of recognition and remuneration as a profession." Approving the enormous increase of central control foreshadowed in the White Paper proposals, he nevertheless writes: "Professor T. Simey has shown that 'political control led to irresponsibility of the permanent official, and to inability to formulate a policy for the administration of a service,' and the 'the problem of reconciling political control with administrative courage and efficiency' still awaits satisfactory solution." He repeats the criticisms already made by the B.M.A. of the present inadequacies of central and local government, but backs up the official line of pursuing what he describes as a "make-do-and-mend" policy for the health services as well as for education, without remedying the existing chaos of local government. Yet the broadsheet admits that Canterbury, with a population of 26,000 will be separately represented on its Joint Board, but no Bexley, with a population of 77,000. The counties of Rutland and Radnor, with populations of 18,000 and 20,000, will rank as major authorities, while Wandsworth (340,000), Islington (292,000), and Harrow Urban District (184,000) will be minor authorities unable to run their own Health Centres. All this seems to be an illustration

¹ *Times*, June 28, 1944.

of the compelling force of what it is contemporary fashion to call an ideology. The facts are ignored so that the theory may remain unstained. In spite of the anomalous exclusion of large authorities from the Joint Boards, PEP sees in the Joint Board the key partner in the area plan. The Joint Board, the broadsheet observes in time, "should never forget its partner—the local health services council." It believes that there would be "little harm and a great deal of benefit from the co-optation to the Joint Board of a few professional members," but "the real place for the expert" is on the Health Council. PEP nevertheless recognizes the risks of local inactivity and central timidity, and in one significant sentence makes this statement: "Much will depend upon the attitude of the Treasury, the effectiveness of the Central Health Services Council, the personality of the Minister, the alertness of his officials, and the political complexion of Parliament." Is it really upon these that the health and well-being of the country is to depend? The individual medical man, be it noted, is not mentioned.

The new doctor will, according to PEP, find his proper place in the Health Centre, which should "be pervaded with an atmosphere of friendliness." "Doctors," it says, "would learn to treat their patients not as irresponsible children but as adult fellow-citizens, and the old-fashioned mystery man would gradually disappear." The doctor in the Health Centre will also have to give lectures on "health topics," and this discipline "will equip doctors and other health workers with that intimate knowledge of the 'consumer' of the health service which they often lack to-day." This is the kind of nonsense to which the medical profession is at the moment being subjected. The medical profession has every reason to suspect the motives of people who write like that. If there is one man in the community who has a real conception of the intimate needs of his fellow creatures it is the practising doctor.

We print in the opening pages of this week's *Supplement* the summary of the broadsheet. The full document should be read widely, as it is an important commentary on the White Paper. It brings to a head a number of issues with which the profession is now confronted, and often, we believe, breathes a spirit which is inimical to the medical profession. It is the spirit which can see no other solution to any problem except through the rigid confining of the individual in an official-bound administrative structure. It is planning—both Political and Economic.

A NATIONAL MATERNITY SERVICE

There will be general agreement that the foundation of a national health policy must be a good maternal and infant health service. The maternity and infant health services committee of the Royal College of Obstetricians and Gynaecologists has prepared a report in which a National Maternity Service is dealt with in its widest aspects, the care of the infant and social and economic conditions being given their rightful place.¹ The practice of obstetrics

must be considered on a broad national basis, in the light of the ideas and needs of to-day.

In the introduction the shortcomings of the present service are considered. It is true that the three obstetric mortalities—maternal, foetal (stillbirths), and neonatal—have steadily fallen during the past few years, and for this due credit must be given to the health services of the country and the way they have been kept going during the difficult years of war. Nevertheless the report states that the pace has been by no means commensurate with advances in general medical science, and is much more likely to have come about from the more prevalent use of blood and plasma transfusion, the use of sulphonamide drugs, and recent bacteriological technique in preventing and tracing contact infection, than from a rise in the average standard of obstetric practice. There can be no doubt, too, that the maternal and other rates could be forced considerably lower by making better use of our present resources. The attention paid in the report to social and economic conditions in relation to a maternity service reveals an outlook not usually found in documents of this kind. It cannot too often be urged that no form of medical activity can be effective if these conditions are poor. The variations in the stillbirth and neonatal death rates, and to a less extent in the maternal rate, according to social class and geographical area, are not well enough known, though the information is clearly set out in the Registrar-General's reports. It is not a pleasant truth that adverse social and economic conditions materially lessen the chances of a child's being born alive and materially increase its chances of dying in the first year of life. Before the war a large proportion of the population suffered from deficiencies in the quality of their diet, and evidence has now been adduced to show that malnutrition is associated with increased abortion rate and premature-birth rate. Moreover, malnutrition may profoundly influence the skeletal development of the foetus *in utero*, leading on to rickety pelvis which twenty years or so later may affect the safety during childbirth of a new generation of mothers. Other socio-economic subjects dealt with in the report are the family unit, the encouragement of early marriage, the mother in industry, home helps, nurseries, and education in sex and parenthood.

The technical section of the report opens with planning, for the best technique loses power unless directed by plans to bring together patients, workers, and equipment at the right time and in the right places. Planning must be based on areas of adequate size. The present system of multiple authorities—there are more than 400 sovereign independent maternity and child welfare authorities in England and Wales—must go, for a small authority has neither the means to provide nor the material to make use of a complete service for itself. The report considers that the maternity and infant health needs of an area with a population of about a million, yielding about 15,000 births a year, would be big enough to make full use of a complete service and, on the other hand, would not be too large for economical administration and central leadership and guidance. At the same time the country should be divided into large health regions based whenever possible on a

¹ The report is published by the College, 55, Queen Anne Street, London, W.1, at 1s. 6d. The summary and conclusions appeared in the *Journal* of June 17 (p. 823).

university medical centre, the aforementioned areas becoming constituent areas of the large regions.

The service, under this plan, would be based on maternity "centres," of which three grades are specified. A key or primary centre would be the regional centre, associated with a university and attached to a medical school for undergraduates, and "of such size, status, and repute that it would be the chief consultative and research centre of the region, as well as the source of leadership and inspiration for all the other workers in the service, whether specialists, general practitioners, midwives, nurses, or lay workers." There would be a whole-time director, of professorial status, living in the precincts. The centre would comprise a unit of 100 or more beds, a department for infants under a paediatrician, an associated gynaecological department, laboratories, ante-natal and post-natal clinics, and it could be the co-ordinating centre for all the maternity work of the region. "Divisional" or secondary centres in large towns and in small towns in rural areas would not necessarily be smaller or less well equipped and staffed than the key centres. At the periphery would lie the outposts of the service, small "local" centres, the focal points in rural parts for midwives and health visitors, with a few beds in charge of selected general practitioners. The relative merits of domiciliary and institutional midwifery are discussed, and the Registrar-General's figures, and figures supplied from large towns, are quoted to show how strong during the past few years has been the trend towards the latter. It is suggested that maternity accommodation should be provided for 70% of all births, the needs of town and country being different. On this basis an area yielding 15,000 births a year would require about 700 lying-in beds and ante-natal beds. As at least one-third of deaths in childbirth are due to shock or haemorrhage, the immediate availability of blood and plasma for transfusion confers at all events one great advantage on institutional midwifery. It is rightly stated that ante-natal care affords

ly a partial protection to child-bearing women, for no amount of ante-natal care can compensate for poor care during labour—quite apart from the fact that certain dangerous complications of labour are unpredictable. The report discusses why ante-natal care does not yet come up to expectations. One of the chief mistakes has been that many local authorities regard ante-natal care as an end in itself, isolated from the labour room, whereas the truth is that pregnancy and labour are all of a piece and should have continuity of supervision from the same doctor. The inadequate provision of ante-natal beds even in modern maternity hospitals is to be deplored; they should be at least one-third of the total bed complement. The report appeals for post-natal hostels and proper rehabilitation after childbirth. In carrying out this ideal there are doubtless domestic difficulties, and that is where home helps and nurseries would come in. Rightly, in so far as the mother is the central figure in the family unit, "plans directed to the improvement of national health must give careful attention to maternal welfare."

The personnel of the service would consist of obstetric specialists, paediatricians, general practitioners, midwives, health visitors, home helps; and all these are considered

in turn. There are at present on the roll of the Royal College of Obstetricians and Gynaecologists 167 Fellows and 285 Members, and even if these were uniformly spread they would scarcely suffice. Here is a problem that demands early solution, for it takes a good five years of postgraduate training to make an obstetric specialist. The Committee of the College states in unequivocal words its belief that, though general practitioners should take an important part in a national maternity service, only those with special midwifery experience and interest should be employed in it. General practitioners with special experience are of two kinds: those who for years have been particularly interested in midwifery practice and have become skilful in that way, and those who after qualification have held a resident post in an approved hospital. The College grants a diploma to general practitioners, and regards the prescribed training as more important than passing the examination. There are at present 332 diplomates (D.R.C.O.G.), a number far short of requirements. "The share that general practitioners would take in the service would be: to have charge of the local maternity centres, to do ante-natal work at clinics and health centres, to do domiciliary midwifery and take medical aid calls from midwives." To encourage the true and desirable team spirit general practitioners should, if they wish, be given opportunities to associate themselves for periods of time with the work in the large maternity centres. It is pointed out that the present system of midwifery practice often places general practitioners in impossible situations where, unsupported by a maternity institution or a consultant or a resuscitation team and in unsuitable surroundings, they may have to deal with complications that would test the promptness and skill of the most able specialists.

Throughout the whole report one theme recurs again and again—co-ordination, integration of all the components of the service, from top to bottom. The weakness of the present system of maternity work in this country is not so much a lack of knowledge as inability to make use of what is already known. And that is where, looking into the future, the report, when discussing administration, ends with a note of disappointment over the White Paper plan of putting the hospital and consultant services under one authority, and the clinics, the general practitioners, and the midwives under another. What is asked for is a service under a single administrative authority.

VARIATIONS IN OUTPUT OF WAR MATERIAL

In order to obtain further information about the vital problem of output in war production factories S. Wyatt and his collaborators, working on behalf of the Industrial Health Research Board, have been making investigations in seven large factories, and they have embodied their conclusions in a report.¹ They planned to measure the individual output of groups of about 200 women workers for a period of four to six weeks before a reduction was made in the hours of work, and for at least twelve weeks after it. Unfortunately the change of hours was not very substantial,

¹ Emergency Report No. 5 of the Industrial Health Research Board 1944 H.M. Stationery Office. (4d)

as they fell only from about 54 hours a week to 51 hours ; but this relaxation of working time was followed by an average increase of 3% in the output during the first and second four-week periods after the change, rising to 6% in the next four weeks. If the observations had been continued for a longer period the rise would no doubt have been greater still, for the occupations studied by the Health of Munition Workers Committee in the last war showed that three months or even more were required before the workers achieved the full production brought about by a shortening of hours. In the present investigations a close inquiry showed that the changes in output often depended, in part, on other factors than the effect of shorter hours, but in three of the groups studied it was possible to infer with some degree of certainty that the shorter hours genuinely increased the hourly output. The effects of various disturbing factors are illustrated in the pamphlet by a series of charts, and they include modifications in design, mechanical and material difficulties, variations in supplies, and technical improvements in the methods or conditions of work. Arguing from the results obtained in this and a previous investigation (Emergency Report No. 2), the inference is drawn that, of all the factors studied in numerous war factories, technical improvements and re-organization are the most likely to lead to an increasingly high level of efficiency.

The effect of hours of work on absenteeism is well shown in two series of data. When the women were working 59 hours a week the average absenteeism was at a maximum of 19%, and when hours were reduced to 55 it fell to 11%. In the men, as a whole, the absenteeism was only half that of the women, and it reached its maximum of 11% when their hours of work were 65 a week. It fell steadily with reduction of hours, till it reached a minimum of 6% when they were 56 a week.

GOOD LIGHTING

The "black-out" and the need for economy in power have interrupted the steady developments of pre-war years in the proper use of lighting as an essential aspect of vision. This interruption in developments and the temporary relapse to lower standards of visual comfort have, however, made people light-conscious who previously took lighting, like many vital but familiar things, for granted. The rebuilding of our cities and towns offers opportunities for the introduction of good lighting as an integral part of civic life, while the vast housing schemes that are inevitable likewise allow for the planning of adequate lighting. The stringency that the war years imposed can but add to the recognition of the need for such innovations, and the Illuminating Engineering Society has done well in clearly formulating desiderata for the future. The general principles underlying illumination are brought out in an introductory pamphlet, and special aspects are dealt with in two separate publications on the lighting of schools and of public buildings.¹ The introductory pamphlet rightly stresses the point that by good lighting is meant lighting that is ample and adequate for the particular task in the particular environment, and that by this standard a vast number of people are still working and living under "appallingly bad" conditions. If it be true that seeing is a partnership between good lighting and vision, it is also true that good lighting is not merely a question of ample quantity. The lighting system has to harmonize with the general architecture, so that abrupt contrasts

between light and shade are avoided. The sickle-like sharpness of the edge of shade and shine of sun-drenched woods and fields is highly undesirable in the home and workroom, and this emphasizes the difficulties of the illuminating engineer trying to enliven an unsatisfactory building. Yet different buildings are planned for different purposes, and the lighting requirements of, say, a picture gallery and a classroom are obviously different. In the one a suitably placed concentrated light, shading off gently into the background, is necessary; in the other a more general and diffuse lighting system is required. Public buildings can add to or mar the natural dignity of a town, and illuminating engineers are right in insisting that the exterior lighting of such buildings and the adequate lighting of their backgrounds are civic problems that deserve consideration. The flood-lighting seen in our cities in the Jubilee Year remains as a pleasant memory and gives an indication of things to come.

CONTINUOUS CAUDAL ANALGESIA

Progress in anaesthesia consists in something more than changing a tap on a piece of apparatus in order to give it a new name. Few really new principles in anaesthesia in recent years are standing the test of time. Continuous spinal analgesia, which may be one of these, was introduced by Lemmon¹ in 1940, and the principle of continuous regional analgesia has since been applied to extradural analgesia administered through the sacral hiatus.

Single-dose caudal analgesia has never been popular in this country because of the occasional difficulty of inserting the needle, coupled with a high rate of failure, even in expert hands; and it has largely given way to spinal analgesia. To these difficulties the continuous method has added the necessity for keeping the needle in place for periods of, maybe, hours, in a site where infection is difficult to eliminate in a patient lying on his back. The possibilities of infection, broken needles, and inadvertent subarachnoid injection are ever present, and in the literature of continuous caudal analgesia form a disagreeable though prominent triad casting a discouraging shadow over otherwise enthusiastic reports. Hingson and Edwards² were pioneers in working out the technique of continuous caudal analgesia for obstetrics. Anaesthesia in labour still leaves much to be desired, and in spite of the technical difficulties enumerated further work on this method is justified, in order that its value may be assessed in relation to other methods of relieving pain in childbirth. A more recent application of continuous caudal analgesia is to abdominal surgery generally.³ Though there is always plenty of room for improvement, present methods of analgesia for upper abdominal surgery can fairly be described as satisfactory—a description one could not apply to analgesia in obstetrics. It is therefore difficult to justify complicated techniques such as extradural analgesia, paravertebral analgesia, or other unnecessarily complicated means of blocking the intercostal nerves for upper abdominal surgery when the end-result is practically indistinguishable from straightforward spinal analgesia achieved by means of the simple injection with which we are familiar. Southworth and Hingson have published their results of 903 operations, most of them on the lower abdomen, in which continuous caudal analgesia was used. This technique is not for the novice, and it is doubtful whether it will commend itself to the expert who already gets good results from simpler methods.

AN INDUSTRIAL REHABILITATION CENTRE

BY

Brigadier F. D. HOWITT, C.V.O., M.D., F.R.C.P.

Consulting Physician in Physical Medicine to the Army

The Ministry of Labour has opened a Centre at Egham for the industrial rehabilitation of male patients. This represents a new experiment in the general field of rehabilitation, and the object is to combine the functions of reconditioning, physical development, restoration, vocational guidance, and purposeful training. It is constructed on the lines adopted in Army practice, which has emphasized the importance not merely of finding a job for a man but of finding the right job for him. It has been realized that the complete employment of available man-power, so essential in total war, demands the complete utilization of the individual. He must be placed in an occupation which fully exercises all his available faculties and not in one which is within the easy compass of his competence. While this holds good for the fit man, it is equally important for the disabled. The Centre is constructed on the lines which the Army has evolved to meet these problems.

Description of Centre

The Centre is situated 1½ miles from the village and railway station of Egham, in 54 acres of park-land. It is under the control of a manager, appointed by the Ministry of Labour, chosen for his wide knowledge and experience of industrial occupations and training. It is equipped with first-class workshops for various building and engineering occupations, and there are also courses for handy-men and gardeners. These facilities, which are all under a highly qualified teacher, are used to test suitability for various occupations, and further provision will be made in the light of experience.

The Medical Officer, who has undergone a course of special instruction, discusses the aptitude and potential capacity of each man with the manager. He co-operates with him in the choice of employment, and regulates progression of training on medical grounds—a most important feature in all forms of rehabilitation. He has a staff of medical auxiliaries, including fully trained physiotherapists, and the remedial gymnastics are in the hands of a senior Sergeant Instructor of the Army Physical Training Corps, released for the purpose from a military convalescent depot.

The Centre contains an excellent gymnasium, a physiotherapy department, and a recreation hall. Provision is made for entertainment, and particular attention is paid to the proper use of leisure. The kitchen and catering are under the supervision of a qualified dietitian. Special care is given to the manner in which meals are served, as the psychological effect of this is considerable.

The course is normally of six to eight-weeks' duration. It is of an active character and is therefore not suitable for men who are still in the earlier convalescent stages of recovery from illness. The Centre does not provide medical treatment or nursing. The following cases are not accepted: (1) men suffering from infectious or contagious diseases; (2) cases of psychosis or severe neurosis; (3) epilepsies; (4) the totally blind. On completion of the course the men go either direct to employment in their previous or in some other occupation, or are transferred to a vocational training centre for a full-time course in the new occupation chosen for them.

The types of case which it is considered would derive benefit by transfer to Egham may be roughly described under the following headings.

Rehabilitation

After all debilitating illness or injury, even when restoration to full functioning capacity is envisaged and will be attained, there is a period between the cessation of active treatment and full employment during which working efficiency remains impaired and accident-proneness is increased. Simple convalescence is not enough. This interval should be bridged by skilfully graduated remedial exercises, directed not only to the restoration of function in the disabled part but also to the mental and physical demands of the future employment. The patient must be progressively and adequately trained so that he can take up a full day's work without fear of relapse or ill effect. This stage can be pursued satisfactorily only when undertaken away from the hospital atmosphere.

Rehabilitation involves the study of the whole man. The physical, psychological, social, educational, and environmental aspects must all be borne in mind. It is one continuous process, beginning at the moment when the patient is deemed to be able to take an active interest in his recovery, progressing through the ambulant stages, and ending with his final hardening to the requirements of his prospective job or of a full-time course of training.

There comes a time, however, in the convalescent stage of all serious disease and disability when an assessment must be made as

to whether the patient can return to his former employment, whether some modification of his original work is necessary, or whether a new vocation must be found for him. Men sent to Egham for reconditioning to the demands of their old employment have, in addition to the remedial measures employed, the advantage of graduated vocational retraining in its various workshops. When, on the other hand, the disability is of such a nature as to preclude continuance of previous occupation or some modification of it, another and more suitable job must be found. Here also the Centre at Egham offers a unique opportunity of deciding, during the period of reconditioning, the type of occupation a man could usefully fulfil and to which he could gradually be trained. Early reinstatement and training for a definite and specific purpose carries with it an added psychological impetus.

Vocational Guidance and Purposeful Training

The more favoured members of the community are able at an early age to make up their minds as to which trade or profession they wish to adopt, and have the opportunity of pursuing it or of taking up another before it is too late. The less fortunate, because of social or environmental circumstances, or because of a short-term policy of economic return, are often lured into a vocation entirely unsuitable. The disabled man is particularly in need of guidance in the choice of his career, and for this he requires the advice both of a doctor versed in the many-sided aspects of rehabilitation and of an expert conversant with the varying demands of the different branches of industry. It is surprising how inept is even the normal but uninstructed individual in the simplest tasks, such as digging, jumping, lifting, and climbing. When dealing with the substandard, correction of faulty technique may not only prevent further disability but may be productive of considerable economy of energy—a point of great importance to the handicapped man.

The attainment of these objects demands a catholic outlook and a wide appreciation of the responsibility entailed, in accurate and careful selection of employment, assessment of recovery, graduation in training on the physical side, and appraisal of the essential psychological and environmental background. Enthusiasm must be engendered, and the whole-hearted co-operation of the individual must be ensured. These objects can only be attained under the twin guidance of a technician who appreciates the nature of the task and of a doctor capable of assessing functional capacity on anatomical, physiological, and psychological grounds.

Skilled vocational guidance is of particular value to the ex-Service man who has been discharged from the Forces with some residual disability. He may have been a skilled worker before the war; or his Service experience may have kindled an ambition for progressive and skilled work of a kind he had not previously contemplated; or he may have gained some technical knowledge in one of the recognized Service trades. For such a man a disability may appear the end to all his hopes, and, left to himself, he may drift into unsatisfactory employment, with the danger that later on, when opportunities are not so easy as at present, he will become a disgruntled citizen. The psychological factor in such cases is all-important. The atmosphere and expert advice provided at Egham should restore confidence and help the man on the road to a useful place in the working life of the community.

Research

The experiment should provide excellent material, collected and controlled by a follow-through mechanism, for group research on a considerable scale into problems of rehabilitation and re-vocation generally. Much information could be collected with regard to restricted function in a wide field of medicine and surgery that would be helpful as a general guide to occupational placement. It is hoped that the Ministry of Labour will develop a service of this kind in co-operation with industrial medicine—which has already contributed so much—by compiling statistics into the occupations open to individuals with specific disabilities, into the aetiology of minor medical conditions which lead to ill-health and reduced efficiency rather than to disease, and into many and varied problems of common interest.

Admission

The Centre was planned to receive patients direct from hospital or within two to three weeks of their discharge. All hospitals in England and Wales have been circularized by the Ministry of Health. A simple certificate (on a form known as R.D.11) from the hospital authorities is all that is required; it is the duty of the Ministry of Labour representative who attends the hospital to explain the details of the course to the patient and to arrange his journey. Application can also be made at any local office of the Ministry, in which case a certificate (on the form R.D.11) is required from the man's private doctor.

The scheme is a voluntary one. The cost, including full maintenance and instruction and fares to and from the Centre, is borne by the Ministry of Labour. In addition each man receives an allowance

of 24s a week for himself with a supplement of 10s a week for his wife and 4s a week for each child. An ex-Service pensioner continues to receive his full pension.

Further information can be obtained from any local office of the Ministry of Labour. The manager of the Centre will be glad to receive medical officers and other members of hospital staffs. The address is the Egham Industrial Rehabilitation Centre, Wood Lee, Egham, Surrey, and the telephone number is LEH 880.

It is hoped that both hospitals and industrial doctors will take advantage of this Centre, for the benefit of their patients.

PREVENTIVE MEDICINE: TEACHING AND PRACTICE

INAUGURAL LECTURE BY PROF. J. M. MACKINTOSH

An address on teaching and practice in preventive medicine was given at the London School of Hygiene and Tropical Medicine on June 23 by Dr J. M. MACKINTOSH, the newly appointed Professor of Public Health, University of London. The chair was taken by Lord WOOLTON, Minister of Reconstruction.

Prof. Mackintosh, who was introduced by Prof. Major Greenwood, began by repeating a definition of social medicine given by Gordon Smith in 1824—"The application of medical knowledge to man in his social state." But the history of public health teaching he said went further back than that. In 1786 Johann Peter Frank was appointed director of public health of Austrian Lombardy, and his international fame led to the creation of the first chair of public health in a British university (Edinburgh). Andrew Duncan, sen., who became professor of the Institute of Medicine in Edinburgh in 1789, began in 1795 a series of lectures on medical jurisprudence, including "medical police"—a term quite familiar to Scottish ears—in which he dealt with both personal and environmental health. In 1798 Duncan presented a memorial as the outcome of which in 1807 George III granted a commission creating a professorship of medical jurisprudence and medical police "as taught in every university of reputation on the Continent."

The Diploma in Public Health

The next landmark was the action of the General Medical Council in drawing attention in 1869 to the desirability of inserting in the *Medical Register* a qualification in State medicine which eventually received sanction in 1886. The action of the GMC was due largely to four men—Henry Acland Stokes of Dublin, E. A. Parkes, and H. W. Rumsey. But even so opinion was divided. Billroth in Germany in order to emphasize the value of the basic sciences in medical education confessed that he was not interested in the struggle for public health and Welch took this view to Baltimore when he became professor of pathology in 1884 though later when Welch set himself to organize his new school of hygiene, he said that he was trying to stress the humanistic aspect of medicine because in the past the whole emphasis had been—and he thought the times had demanded that emphasis—on the scientific side.

In England the institution of the DPH arose in response to a specific public need for officers of health when bacteriology opened up a new field of study. A generation ago it was reasonable that medical officers of health should be expected to supervise bacteriological and chemical work. As recently as 1925 one or two medical officers of health were still public analysts for their areas. The immense broadening of the fields of bacteriology and applied chemistry inevitably led to specialization and medical officers of health burdened with increasing administrative duties, were forced to leave laboratory work to experts—a tendency accentuated by the provisions of the Local Government Act 1929, and by the various Housing Acts.

The changes in health policy which took place up to the end of the last war were only feebly reflected in the diploma course. As recently as 1920 British universities, speaking broadly, took no cognizance of the DPH. To gain experience in public health administration the student was usually left to shift for himself, the course was not as a rule well knit,

and in some cases the teaching fell lamentably behind the needs of applied practice. It had often been said that there was a great gap between the establishment of scientific knowledge and its application to human needs. This was partly due to economic causes, partly to lack of administrative machinery, and partly to insufficient diffusion of knowledge.

Colleges of Preventive Medicine

The primary importance of a school or university department of hygiene Prof. Mackintosh continued, was to make good practitioners of health to send out competent men and women with a high sense of their calling and a scientific outlook. It was easy to speak these brave words and difficult to translate them into organized teaching courses, but there were certain guiding principles.

(1) No school or university can create a scientific outlook in its students unless it is actively engaged in research in the basic sciences—that is to say sciences for the advancement of knowledge irrespective of immediate practical considerations.

(2) The department should direct the application of scientific work to problems of public health—for example through surveys, routine laboratory investigations, statistical and epidemiological studies, and field experiments.

(3) The department should be strictly associated with current administration, including housing and sanitation institutions and hospitals, and the everyday duties of the practising M.O.H.

(4) The department should co-ordinate the postgraduate course for the DPH by means of direct teaching of the principles of preventive medicine in order to weld the course into a coherent whole. It was the duty of the professor of preventive medicine to see that the course as a whole was complete, sound in structure, balanced in emphasis, and sufficient as a framework on which to build experience.

The earliest examples of schools designed as colleges of preventive medicine were the School of Hygiene and Public Health at Johns Hopkins University, the University of Toronto School of Hygiene, and the London School of Hygiene and Tropical Medicine. All these drew much of their inspiration from a report prepared in 1915 by W. H. Welch and Wickliffe Rose and presented to the General Education Board of the Rockefeller Foundation, and none of them could have achieved success without that Foundation's support. A school of this kind, especially when it catered for the needs of graduate students, must necessarily have a large staff for teaching and research. It must enlarge its borders far beyond the ordinary university school or department. It should aim at offering exceptional opportunities for graduates, but it should not offer diplomas in special subjects nor should it directly provide clinical instruction, although it might make arrangements to that end.

Organization of Teaching Courses

The type of organization which best provided for intensive study and research and general instruction was the system of basic and elective subjects which obtained at Johns Hopkins University. This had the advantage of flexibility. As for clinical instruction the right approach to clinical medicine was through the training of a physician, and this applied equally to tuberculosis, venereal diseases, infectious diseases, maternity and infant welfare and child health. The health officer must of course have enough knowledge of these matters to enable him to administer with understanding the community services which dealt with them. A term of residence in a fever hospital was a valuable experience for a health officer, but it did not of itself make him an expert in infectious diseases, for which he would require a background of medicine and paediatrics. Similar considerations applied to tuberculosis and venereal diseases. The course should be chosen in order to train men and women to be competent administrators both of institutions and of public health services generally, but the course was merely an introduction to administration and must be followed by practical experience in institutions and health departments. There was a feeling in this country that administration could not be taught academically, and that only what was called practical administration was of any value to the student, but it would be a poor preparation for a career in preventive medicine if students acquired knowledge of a subject without any background of the wider principles of administration.

With regard to teaching, he contented himself with the following headings:

- (1) The historical background of the public health and social services.
- (2) Central and local government.
- (3) Elements of national health policy, including both environmental and personal health.
- (4) The law relating to public health.
- (5) Principles of medical administration, both institutional and departmental.
- (6) Public education in the promotion of mental and physical health.
- (7) International health relations.

After describing the White Papers on the National Health Service and on the Government employment policy as "valuable prescriptions from the pharmacy of social medicine," Prof. Mackintosh said that those concerned for the future of public health must be "fearless in devising, ready to cast out intolerance and partisan advocacy, and unafraid of new plans for co-operative action, even when they ran counter to traditions."

Lord Woolton on the White Paper

LORD WOOLTON, from the chair, speaking of the White Paper on a National Health Service, said:

"I understand from the newspapers that certain practitioners in the [medical] profession have some doubts about the conditions of their service under the new plan. I beg them not to be unduly fearful. Terms are a matter of negotiation, but the end at which we are aiming cannot be a matter of controversy. The aim is that to every man, woman, and child in this country all that is best in medical science shall be available. Medical need can have no concern with capacity to pay. The medical profession has a long and glorious career of benevolence in the public service, but in spite of all their best endeavours there remains in our midst much suffering and physical incapacity which I am given to understand is preventable. Common humanity demands that we should address ourselves to this problem and seek and find a solution to it. On grounds of sentiment—which are not to be despised—and on grounds of the economic health of the nation we must deal with this issue of physical ill-health. We cannot afford the loss of capacity or the loss of time that comes from physical disability, and, with great respect, I invite practitioners of this great profession to refrain in discussion from anything which brings about that friction that leads to heat rather than to light. I invite them to join with those of us who are in public office and who are seeking that the way shall be open to an even larger field for their healing skill. For we must succeed. The public good must be served, and the doers of good must have both opportunity and just reward."

Reports of Societies

HOSPITAL PROVISION FOR SMALLPOX

At a recent meeting of the Fever Group of the Society of Medical Officers of Health Dr. ANDREW TOPPING, the President, opened a discussion on smallpox, with special reference to hospital provision.

He said that memories of the ravages of variola major in this country 50 years ago led to the perpetuation of innumerable small *ad hoc* smallpox hospitals, although improvements in ordinary sanitation and control of infection made it unlikely that the disease would ever sweep the country again in epidemic form. As the theory of aerial convection had proved untenable, an occasional case of smallpox, actual or suspected, could justifiably be admitted to a single-bed ward in any modern fever hospital if staff and patients in contact were protected by vaccination. But administrative difficulties might be considerable, and public opinion would weigh against such a practice. The number of reserve smallpox hospitals was needlessly great, and he favoured self-contained units of 4 to 20 beds, with accommodation for observation, within the curtilage of larger hospitals. If an outbreak assumed epidemic proportions all or most of the hospitals could be taken over temporarily for cases of smallpox. A service of experienced consultants was necessary (as already existed in London), also a reserve of vaccinated nursing and ancillary staff bound by

their terms of service to undertake duty in smallpox cases if required.

Method of Spread

These views might appear controversial, Dr. Topping continued, but in his view every case of smallpox could be accounted for by ordinary methods of spread *if a complete and accurate history of contacts and movements could be obtained*. Earlier supporters of the theory of aerial convection in the neighbourhood of smallpox hospitals too often ignored the possibility of a breach of control regulations by a member of the hospital staff. On the question of whether vaccination did protect, he said, it had to be admitted that with single-insertion methods they were on less sure ground, but recent experience of major smallpox showed that even minimal vaccination exercised a definite protective or modifying effect. He favoured a return to adequate vaccination standards in the presence of the major disease. Small units in the curtilage of larger hospitals on the lines he had suggested could be used for other purposes when not required for smallpox cases. A larger hospital as second-line or reserve accommodation would be necessary, such as a fever or convalescent hospital whose ordinary patients could be evacuated without serious dislocation. It might be argued that the moment was inopportune to suggest changes of this nature, and that war and the rapidity of modern travel added to the risks of a smallpox outbreak, but he saw no reason to think that an epidemic serious enough to cause a breakdown in public health control was likely. It was preferable to have a comparatively small number of beds ready at short notice with staff and equipment rather than a thousand beds on paper, the majority of which were unstaffed and unusable.

Clinical Picture in Recent Outbreaks

Dr. A. JOR, describing the Edinburgh outbreak of 36 cases, said they fell into two groups: (1) 23 institutional cases, and (2) 13 city cases, of which 5 were direct contacts of other city cases. The source of infection of the institutional cases was never disclosed, nor was the association of these with the city cases or the primary city cases with each other. The rash in its early stages in the first case had much in common with chickenpox, and it was not until it was fully out that a confident diagnosis of smallpox could be made. The second case was sent in as of cerebrospinal fever, and in the first few hours after admission was clinically more characteristic of that condition than quite a number of the 600 cases he had seen since 1940. The clinical types were: haemorrhagic 6, confluent 5, semi-confluent 3, discrete 10, and discrete sparse 12. All the haemorrhagic and 2 of the confluent cases were fatal. The commonest symptoms of onset were headache, chill, nausea or vomiting, backache, and malaise. Pyrexia was usually well marked in the initial stage, and only one definite prodromal rash was seen. The true rash appeared most commonly on the 4th and 3rd days, although it was delayed in some cases until the 5th or even the 6th day, and in certain patients it came out on the sides and root of the neck. The disease followed the usual textbook course. Of 9 unvaccinated patients 2 died, and of 18 vaccinated 6 died; there were no deaths among a further 9 who had been vaccinated or revaccinated. In four of the fatal vaccinated cases more than 50 years had elapsed since vaccination, more than 40 years in another, and at least 24 years in another patient who was suffering from bilateral hydronephrosis when he contracted smallpox. There were 15 cases of successful vaccination or revaccination during the incubation and initial periods of smallpox, 2 of these occurring 12 days before the outcrop of the true rash, thus disposing of the textbook statement that vaccination in the first three days after exposure would always protect. Successful revaccination in one case 7 days before the true smallpox rash failed to avert a fatal haemorrhagic attack. Sulphonamides were used in the treatment of 14 cases. No spectacular results were obtained at any stage of the disease, though there was a relative absence of eye and lung complications, and raw surfaces healed rapidly. When the Glasgow outbreak started every member of the hospital staff was revaccinated, and within a few days of the confirmation of the Edinburgh cases practically all patients except the seriously ill were protected, refusals being only 0.5%.

At one stage of the epidemic the smallpox hospital was nearly full so it was decided to put the female patients in a separate small pavilion in the fever hospital. This consisted of two modern four-bedded wards with the usual annexes, and the highest number of patients housed at any one time was 6 the nearest building being a fully occupied two storied diphtheria pavilion 80 feet away. The staff were isolated and accommodated separately from the main hospital so that the conditions were comparable with those suggested by Dr Topping. The experiment was completely successful so far as it went but the number of patients treated was limited, the nursing staff were of the highest order, while the specific immunity against smallpox was kept at a very high level in the patients and staff of the fever hospital. Recent experience of the results of haemorrhagic and confluent smallpox had convinced him that this last condition must be rigidly fulfilled if smallpox isolation was to be carried out within the curtilage of the fever hospital.

Discussion

In the discussion which followed, Dr W. G. PATERSON said that one advantage of attaching smallpox hospitals to the larger fever hospitals would be ease in providing expert medical supervision. The offensive odour normally associated with severe smallpox was not a feature of recent cases in his care nor had there been extensive scarring. Dr A. F. CAMERON thought that treatment in small units inside fever hospitals was feasible provided there was (a) a reliable staff, and (b) complete separation of staff, but the human factor required careful watching. Dr C. A. BENTLEY'S experience in India was that the erection of *ad hoc* smallpox hospitals far removed from the villages made it impossible to control irregular visiting. In Calcutta the smallpox hospital consisted of two pavilions in the grounds of a general hospital. There was no evidence of spread in the vicinity, but much depended on vaccination and revaccination of patients and staff. A single insertion, he said, could not be relied on to protect against Asiatic smallpox, three or four insertions were required. Vaccination up to 3 days after exposure gave a high, but not absolute, protection.

Dr H. S. BAXS described a toxic illness of high infectivity among smallpox cases. If this was primary smallpox it did not appear to be transmissible, and he wondered if this meant that infectivity was not high before the focal rash appeared. There would be obvious advantages in attaching smallpox hospitals to fever hospitals, but he thought nobody would wish to treat variola major near a fever hospital without vaccinating all the fever patients. Dr J. PICKFORD MARSDEN pointed out that Ricketts had never promised immunity to those vaccinated early after exposure to smallpox, preventive vaccination was always to be preferred. The value of sulphonamides was difficult to assess because partial immunity had the same effect on the behaviour of the rash as was often attributed to these drugs. They could add to difficulties because they occasionally produced a rash mimicking pustular smallpox. He stressed the importance of an adequate observation unit which need not form part of the smallpox hospital. He thought the arguments for and against aerial convection were unimportant, what mattered was that the disease tended to spread in the vicinity of smallpox hospitals. Still, a strong case could be made for attaching smallpox hospitals to fever hospitals, but such units should be made completely self-contained.

At the last meeting of the Manchester Medical Society Dr EDITH PATERSON demonstrated by cinema film the technique of growing *in vitro* bone cells from fragments of avian embryo bone. The behaviour of the cells which emerge from the explant—macrophages, monocytes, osteoblasts and osteoclasts—was demonstrated at low and at high magnifications. The similarities of round mononuclear cells to osteoclasts was shown by the similarities of movement and of staining and the possible relation between these two types of cells was discussed. A group of mononuclear cells, it was shown, could fuse together to form a multinucleated cell and multinucleated osteoclasts shed small mononuclear cells. Mitosis was easily demonstrable in osteoblasts, but had not in the author's experience ever been seen in an osteoclast. The life of an osteoclast *in vitro* was short. Osteoclasts could "eat" their dead or dying fellows; they could also ingest the protein of the plasma and foreign matter introduced to the medium. *In vitro* they could not be shown to attack bone fragments.

Correspondence

Treatment of Wound Shock

SIR.—In view of the immediate practical importance of diffusing rational ideas on the treatment of wound shock, Dr. Martinez Alonso's letter (July 1, p. 21) calls for comment.

1 *Technique of Blood Transfusion*—Dr Alonso suggests that rapid transfusion may be harmful and thinks that slow drips give better results. This is entirely contrary to experience in civil and military casualties in this war. When the blood pressure is low as a result of haemorrhage the sooner it is restored to normal the better, and rapid transfusion is eminently desirable. It is only after the blood pressure has been restored to normal that the transfusion is slowed to a drip.

2 *Definition*—The second paragraph implies that haemorrhage may complicate shock. Most clinical workers are agreed that haemorrhage is the major cause of shock in wounded men (Whitby, Wilson, Grant, and others).

3 *Pharmacological Remedies*—Recent research in this school (*Lancet* 1943 1, 637, *Clinical Science*, 1944 in press) indicates that the human body has mechanisms which maintain an adequate circulation when the blood volume has been slowly reduced. The mechanisms probably involve constriction of the peripheral venules to restore an adequate pressure in the great veins near the right heart. A pharmacological substance which would act thus on the venules would go a long way to the solution of the problem of shock. So far such a substance has not been found.

Clinical work, however, is well known to produce remedies before the scientific pharmacological laboratories, and Dr Alonso's experience is of great interest. In the case he describes the obviously low blood pressure, the "occasional heart-beat suggesting a slow pulse, and the accompanying unconsciousness make it almost certain that this was an example of vasovagal fainting after haemorrhage. As has been shown in this school (*Lancet* 1944, 1, 489), this is a special type of reflex collapse with profound muscular vasodilatation. In this type of "shock" vasoconstrictor drugs such as pholedrine and methedrine may well be of therapeutic value.

In acute oligæmic shock with a low blood pressure and a rapid pulse it seems dangerous in our present state of knowledge to recommend pharmacological remedies when the value of adequate transfusion has been so abundantly proved. The excellent transfusion arrangements provided for the Services and for the civil population can be relied on to meet almost any demands—I am etc.,

JOHN MCMICHAEL.

Results of Colles's Fracture

SIR.—In his analysis of Colles's fracture (June 17, p. 807) Mr S. C. ROGERS makes no allusion to the influence of sex upon the prognosis. It has fallen to my lot to see a large number of these injuries in their later stages, and it has been noticeable that the most unfavourable results have all been in women, owing to their special liability to arthritis of the fingers and metacarpophalangeal joints. In the worst cases the impairment of grasp was so great as to involve a complete loss of the function of the hand. In all such cases the women had been treated by immobilization of the fracture in plaster-of-Paris for several weeks, usually five or six.

The type of arthritis so common in the hands of women is aggravated both by trauma and by restriction of movement and disuse, and there is evidence that the absence of movement is a more potent deleterious factor than the trauma. I have seen quite a number of cases in which the fracture had not been diagnosed till long afterwards, and in which the only fixation employed had been the household application of a bandage. All of these women escaped the crippling arthritis, so that the hand remained a useful member, notwithstanding the deformity and the impairment of pronation and supination and of the movements of the wrist.

The bad results of prolonged immobilization do not occur in the practice of skilled orthopaedic surgeons, but that they

occur at all makes it desirable to point out that in the presence of Heberden's nodes or other signs of arthritis fixation by plaster-of-Paris should be used with great caution, and only for short periods; five weeks in my opinion is far too long. This warning is not confined to the treatment of Colles's fracture, for a minor injury to the hand in a woman with Heberden's nodes may readily be converted into a grave and permanent disability by the use of a plaster-of-Paris bandage. Above all, complete freedom of movement should be assured to the metacarpo-phalangeal joints, for these joints are liable to a rapid and destructive arthritis without example in any other region of the body.—I am, etc.,

Edgar Allen Institute, Sheffield.

The Site for Intramuscular Injection

SIR,—In one of the latest memoranda from the War Office the writer mentions, almost with tacit recommendation, the injection of penicillin "into the gluteal or other suitable muscles in the usual way." In the *Lancet* for Oct. 16, 1920, I drew attention to "the site for intramuscular injection," and I feel it a duty once again to point out that the gluteal region is a very unsuitable place for this purpose. After the last war several soldiers were the victims of very severe and persistent neuritis or paralysis affecting the great sciatic as a result of the injection of quinine solutions into the nerve instead of into the mass of gluteal muscle. A case in which death resulted from sloughing also came to my knowledge. After the malaria epidemic in Ceylon there were at least two cases of severe secondary haemorrhage from the superior gluteal artery complicating abscess due to the injection of quinine into the buttock and requiring ligature of the main trunk of that vessel.¹ In 1941 A. W. Frankland stated in your columns (*B.M.J.*, 1, 33) that if solutions of sulphapyridine are administered deeply into the gluteal region there is grave danger of injury to the larger branches of the sciatic nerve. He quoted six cases of foot-drop with varying degrees of anaesthesia, also cases of gluteal paresis so that the patients were unable to fix the pelvis. Quite recently one of our larger provincial hospitals was mulcted in damages amounting to several hundred pounds because a patient developed sciatic paralysis after an injection made into the gluteal region.

May I again urge that the outer side of the thigh is the proper place for such injections. The vastus externus is a very large muscle; it is protected by the fascia lata and is not traversed by any important vessels or nerves. The muscular mass is of large capacity, and as much as 500 c.cm. can be introduced into its substance at a sitting provided the injection is made slowly and deliberately. The technique is very simple.

Point on the middle of the outer side of the thigh is selected, the hollow needle is thrust in at right angles to the surface. It is enough to insert it just beneath the fascia lata—a point which can readily be determined by the sensation of the yielding resistance after its penetration or by introducing the needle to an average depth of about an inch from the skin surface. If the needle strikes the bone no harm is done provided always that it is withdrawn for about half an inch before the injection is made. Should necessity demand, injections of small bulk may be repeatedly made into this situation. It would seem reasonable to vary the area of injection by starting near the top of the thigh and working down to about three inches above the knee; or the outer side of the opposite thigh may be used alternately. Of course if a particularly irritating solution is injected or if infection is introduced an abscess may result; but that is about the worst that can happen, and at all events I am unaware of any other complication. As my former house-surgeons B. R. Billimoria and E. E. Dunlop point out² the risk of phlebitis and generalized systemic infection associated with rigors is eliminated. I frequently refer to this matter in teaching, whether by word of mouth or in writing, and I feel sure the profession ought to pay some little attention to the problem, for it is of much importance at the present time, when numbers of young men are called upon to assume unwonted responsibility.—I am, etc.,

G. GREY TURNER.

Unusual Ear Conditions

SIR,—I have seen several ears that have been treated with glycerin of carbolic drops in which there have developed large perforations not due in my opinion to any middle-ear disease, and I have suspected a destructive action due to the drops. It has occurred to me that the glycerin, which inhibits the destructive action of the carbolic, may have been omitted or diluted on account of the difficulty of getting it now. Unless it can be certain that the glycerin is in full strength perhaps it would be as well to prescribe drops containing camphor.

Another type of ear trouble seen a lot to-day is that due to gunfire, and this is largely due to no ear protector being worn. The solid rubber plug is not worn because the wearer cannot hear orders, etc., when it is in the ear and cotton-wool is inadequate. A cotton-wool plug loaded with grease is better, but of course a valve protector coming into action only with blast as used in the Spanish War is best.—I am, etc.,

London, W.1.

C. HAMBLIN-THOMAS.

Sulphonamides in Otitis Media

SIR,—I am grateful to Mr. G. H. Steele (June 24, p. 854) for his comments on my article of June 3 and for ventilating the subject. I am in agreement with most of his statements and in disagreement with some others, so perhaps the matter requires further clarification.

Much confusion arises from the use of the terms "acute ear" or "inflamed drum"; they really mean nothing at all, and give no indication of the nature, severity, pathology, or site of the otitic involvement. External haemorrhagic bullous otitis or herpes oticus on the one hand, or acute suppurative otitis media on the other, can all be called "acute ears" or "inflamed drums," but in their pathology and indications for treatment they are poles apart. The use of the correct label for each of the many otitic infections clarifies the indications for giving sulphonamides, and there was no intention in my article to convey the impression that they were contraindicated in all types of otitis. If my article is carefully read it will be seen that my remarks applied to acute suppurative otitis media, and my contention is that pus locked up in any part of the ear requires drainage first and foremost, and possibly the sulphonamide drugs later.

You may have acute otitis externa, acute catarrhal otitis media, acute otitis media, or acute suppurative otitis media; you may have some of the fulminating types found in influenza or the acute specific fevers. Are all these types to be included under the label of "acute ears," as if they were one clinical entity? Hence my statement that "wholesale use of sulphonamide drugs in otitic infections is to be deprecated," and this I in no way retract.

Many cases of the catarrhal and acute types are never going on to suppuration and may safely be aborted in the earliest stages by sulphonamides. In such cases the patient may have a fairly severe earache, a raised temperature, no appreciable degree of toxæmia, and is not acutely ill. Examination of the drumhead reveals a much-reddened membrane, possibly with bullae, but usually no bulge. Such cases usually resolve with sulphonamides, and sometimes without them. If they progress unfavourably and the general and local condition deteriorates, then the dosage may have been inadequate or the use of the drug as a first line of attack has been incorrect.

On the other hand, many cases are suppurative almost from the start or will rapidly become so; the patient is ill, the temperature is higher, the pain often very severe, and the evidence of toxæmia obvious. The drumhead bulges or pulsates and the usual landmarks are obliterated. Pus may be seen through the bulging drumhead. I feel that it has been the attempt to abort such infections by sulphonamides that has caused Mr. Steele to be disappointed in myringotomy, which I think should have been the first and not the second line of attack.

One of the reasons why the number of mastoid operations has decreased in recent years, and even before the introduction of sulphonamides, is that otologists are, almost without exception, much more conservative in opening the acute mastoid than they were ten to fifteen years ago. Very many mastoids done at that time would have got perfectly well if they had

been left alone for a few weeks, and I will certainly concede that many other operations of the same nature have been avoided by a judicious use of sulphonamides.

I cannot altogether agree with Mr Steele that the general practitioner should be the real authority on the value of chemotherapy in these cases. Most otologists require at least a year of otoscopic experience in the department before they are competent to diagnose all the different varieties of acute otitis via the speculum, and valuable as the general practitioner's contribution will always be in his knowledge of his patient and the constitutional aspect of the illness, I do not feel that his opinion on the otoscopic appearances, which are, after all, all important, can be of greater value than those of the otologist, in just the same way the ophthalmologist's opinion on the fundus oculi must be of greater value than that of the general practitioner—I am, etc.

London W 1

A R DINGLEY

SIR—Mr Dingley's able article on the dangers of sulphonamide therapy in middle-ear infections (June 3 p 747) prompts me to ask certain questions.

Much has been said recently about sulphonamides "masking the symptoms and distorting the clinical picture." What symptoms does a sulphonamide mask and how does it do it? The important symptoms of otitis media and mastoiditis are pain and symptoms due to toxæmia. The important signs are the appearance of the drum and the mastoid process, the degree of tenderness over the mastoid process and the temperature. Surely any drug which relieves pain will do so irrespective of the cause of the pain. Morphine will relieve the pain of a ruptured peptic ulcer and so mask the picture but I don't think anyone will suggest that sulphonamides will do this. So sulphonamides are not analgesics *per se*. If sulphonamides can mask toxæmic symptoms in otitis media why are they powerless to do this with a virus-pneumonia for example? If sulphonamides are antipyretics they should have this effect irrespective of the cause, as a true antipyretic would—e.g., a tepid bath.

To sum up surely sulphonamides act as analgesics, antipyretics will relieve toxæmia and reduce all signs and symptoms of disease by destroying the cause—i.e., the bacterial cause. That is why these drugs are so wonderful—because of their bactericidal effect. This does not constitute "masking symptoms and distorting the clinical picture" but curing the disease. Following this line of thought, when the redness of the drum, the mastoid swelling and the pain and toxæmia are diminished by sulphonamides the infection is necessarily being overcome. Bone infections are notoriously prone to recrudescence, and mastoiditis is no exception. But it is one of the few bone infections which is generally due to the streptococcus and therefore can be influenced by sulphonamides.

If sulphonamides are given in full doses 48 hours will suffice to know whether any benefit can be derived from this therapy. The presence of pus will always indicate surgical treatment, and sulphonamides will not prevent the symptoms and signs due to this pus. I have been giving 1 g of sulphathiazole every 4 hours, even to the youngest child with otitis media, for 48 hours, and, if the condition is subsiding, a smaller dose until the temperature has subsided and been normal for 3 days. No case which under my care has completely subsided with this treatment has as yet recurred, and operation has been avoided. It is the early otitis media which will respond well to sulphonamide therapy, if in adequate dosage. If Mr Dingley persuades practitioners to abolish all chemotherapy with these cases he will undoubtedly give the ENT surgeon more work.

I put forward these views humbly, knowing that my experience is as nothing compared with that of Mr Dingley, but nevertheless hoping my remarks may arouse some criticism and comment—I am, etc.

Timing of Schafer's Method

SIR—Study of first aid manuals brings to light the surprising fact that the timing of Schafer's method is given differently by different authorities. I refer not to the actual rate of respiration but to the ratio between the duration of the expiratory and inspiratory phases.

In the Royal Life Saving Society's booklet the following instructions are given: "Each such double movement will occupy about 5 seconds, two of which may be taken up by pressure (expiration) and three by relaxation (inspiration)." *First Aid to the Injured* (the St John textbook) also states, "The rhythm is, pressure 2 seconds and relaxation 3 seconds." A different timing is given in *R.A.M.C. Training*, 1935, chap 37, para 677, as the following extract shows: "Lean forward and so produce a firm downward pressure on the loins this part of the operation should occupy the time necessary to count slowly one two three. By this means the air is driven out of the patient's lungs. Immediately after this, swing backwards, rapidly releasing the pressure, when air will enter the lungs. This part of the operation should occupy the time necessary to count slowly one, two."

No doubt either method of timing might be equally successful in practice, but surely there should be uniformity in teaching! I consider that the timing given in *R.A.M.C. Training* 1935, is to be preferred for two reasons. First, it reproduces the normal respiratory rhythm, in which a pause of about one second occurs at the end of expiration. Secondly, it is practically identical with the timing given for Eve's rocking method, in which the head-down phase (expiration) is longer than the foot-down phase (inspiration). The advantage of having one timing for both methods will be obvious to all who teach first aid—I am, etc.

Crowthorne Berks

E F CHAPMAN

Chemoprophylaxis of Gonorrhoea

SIR—With reference to Dr Forgan's letter in your issue of June 24 (p 855) two points arise.

(1) If "a warning is wisely uttered against the use of oral sulphonamides for this [prophylaxis] purpose" does not mean much the same as "this method of prophylaxis is not without danger words have no meaning though perhaps 'concerning' would have been a more suitable word than 'against'."

(2) If medical practitioners are not dissuaded from prescribing on the day following exposure 6 g of sulphathiazole or sulphadiazine one is led to wonder how many individuals will become sensitized to these drugs and how much latent gonorrhoea there will be amongst the population—I am, etc.

YOUR REVIEWER.

Industrial Dermatitis

SIR—Dr Howard Mummery in his memorandum on the prevention of industrial dermatitis (May 13, p 660) states "Barrier creams, for which so much is often claimed, have their uses, but in my experience they are disappointing, and necessarily depend too much on the intelligent co-operation of the workman." Barrier creams hitherto available have been disappointing but modern creams can and do afford an efficient barrier against causes of industrial dermatitis.

The washing facilities which he claims are available in his factories appear to be greater than those available in most industrial organizations. This company employs in its machine shops many hundreds of workers who come into daily contact with cutting oils, soluble oils of various types, and organic solvents and as the result of methods employed to prevent dermatitis even when facilities for washing were not perfect and including the many thousands of workers in our assembly plants who come into contact with such dermatitis causers as plastic varnishes and cements, alkalis, acids, etc., there have been only two cases of notified industrial dermatitis during the past year. There have been a number of rashes of various types due to sensitization from industrial products and also exacerbations of exogenous dermatoses due to varying causes. These have all been treated on modern dermatological lines with no loss of working time.

Dr Mummery's method of cleaning demands just as much co-operation from the workers as does the use of a barrier cream, and I feel that had the correct barrier creams been employed there would have been no need to use any special cleanser beyond the ordinary methods available in most engineering shops. The suggestions made by Dr Sybil Horner, H.M. Medical Inspector of Factories, for the prevention of

industrial dermatitis are in my opinion the best to date—i.e., (a) selection, (b) protection, (c) inspection, and (d) cleanliness—and until all of these are adopted in industry the position with regard to industrial dermatitis will not improve.

I am keeping a record of those cases of industrial dermatitis which present themselves to the skin department of the Royal Northern Hospital, and it is interesting to note that practically all come from small factories with few employees, and in many of these no facilities are provided for washing beyond a bucket and some cold water. All types of reagents are used, and there appears to be no selection of the operator for the work in question and no prevention is adopted as cases recur in these factories. There appears to be little or no co-operation between employer and employee. Industrial dermatitis should hardly exist in large factories, because with adequate supervision and prevention the problem is not a difficult one to overcome.—I am, etc.,

London, N.5.

Inquiry into Diabetic Care

SIR.—The Diabetic Association has recently circularized many hospitals in Great Britain with the object of discovering the nature and extent of the facilities at present available for the care of diabetics in this country. The association is eager to make this survey as complete as possible. May I, therefore, through your columns, ask any individual practitioners, clinics, or hospitals who provide such facilities and who have not already received the association's circular to write to the secretary, the Diabetic Association, 9, Manchester Square, London, W.1, so that the circular may be sent to them.—I am, etc.,

C. M. FLETCHER,
Secretary, Medical Subcommittee, Diabetic
Association.

The Cat's Milk

SIR.—A month ago our cat had kittens, and this event set me pondering again about the increasing failure of women to suckle their babies. Breast-feeding has always been more easy among the poorer classes, and usually in domiciliary than in hospital practice, though everywhere it is decreasing in spite of propaganda, increased food, vitamins, expert attention, etc. Why? The cat certainly had no difficulty in establishing adequate lactation. Once again, Why?

The thing that struck me most forcibly was the instinctive way in which the kittens, almost as soon as they were born, found their way to the cat's nipples and began to suck. Is it possible that the close nestling of the kittens against their mother and the frequent stimulation of her breasts had an important influence in promoting lactation; and is it possible that the relatively modern practice of removing the baby at once to a cradle is really the main reason for the present difficulty in breast-feeding? We all know how palpation of a breast will cause stimulation and erection of the nipple, and we also know that tactile stimuli in other areas will cause all sorts of emotions and alterations of function. It is, therefore, not inherently improbable that our modern methods of treating parturient women are actually removing those very stimuli which Nature has depended on for the efficient establishment of lactation. I am not asking for the vituperation of obstetricians for this suggestion (though I may get it), but I should like to know whether there are any reliable data on the subject, for in view of its importance and the recently proposed national maternity service our leaders should surely be able to give an unequivocal and scientifically supported answer.—I am, etc.,

W. N. LEAK.

Progesterone

SIR.—Mr. D. G. W. Clyne seems to suggest (June 24, p. 856) that I claim for my own the progesterone causation theory of vomiting of pregnancy. In my necessarily short note on that subject (June 3, p. 772) I made no such claim, nor on re-reading it can I or my colleagues see that any claim is implied. I was taught as a student that one of the many theories on causation of vomiting in pregnancy was excess progesterone/deficient

oestrin. Since then I have tried the effect of progesterone on isolated rabbit's intestine. Relaxation was produced, but as I was unable to persuade the gut to regain its tone I could not be sure that the effect was physiological rather than toxic, and therefore did not pursue the matter.

I acknowledge the value of personal communications from Mr. Clyne, in one of which he pointed out the further ramifications of the progesterone theory. If I did not then assume that he claimed it as his own, why should he now impute the claim to me? That this inference from my note is not universal is proved by Dr. W. I. Hardy (June 24, p. 862). He says: "Dr. Calvert supports the theory . . . etc." (my italics).

It emerges that Dr. Hardy also supports the theory, of which he was obviously previously aware. So apparently does Mr. Clyne. If, as he says, Mr. Barton Gilbert originated it, then we all, no doubt along with many others, support Mr. Barton Gilbert.—I am, etc.,

Stockport.

WALTER CALVERT, D.R.C.O.G.

Why Tie the Cord?

SIR.—In answer to Dr. E. W. Price (June 3, p. 772) I would say there is no need to tie the cord if the scissors are blunt. Animals nip the cord with their teeth; many native races pinch it off with their nails or use a shell or bit of tin. It is the crushing of the tissues that stops the bleeding. In France (Benouville Maternity) a small clamp was used for 24 hours only.

I should like to ask Dr. Price if he does not find leaving the maternal end to bleed an advantage. In the natural position, squatting or kneeling, this diminishes the bulk of the placenta and should lead to early expulsion and good uterine contraction.—I am, etc.,

London, N.W.11.

KATHLEEN VAUGHAN.

Marriage and Parenthood

SIR.—In saying that 'contraceptive advice may very rarely have to be given to a couple before the birth of their first child, Dr. Saklatvala (April 29, p. 603) raises an old hare which I do not propose to follow except to say that contraception having come to stay it is our duty to see not only that the public use it with discretion and purpose but that they know what to use, when to use it, and how to achieve maximum security—the possibility of which is now extremely high. Thus, as almost every young couple consider these matters and are always trying to get adequate information, it is our duty as doctors to give them the best advice we can, and, if they require further help, to see that they get it from the best sources.

Incidentally, when are doctors going to discontinue the habit of advising women about contraception without examining them, or of fitting them ineffectually when they do examine them? They would never treat an eye condition so haphazardly. Why do they, therefore, the sex organs? If they cannot do the job properly why not send them to people who can? The misery and unhappiness that follow from ineffective advice are often profound and quite unnecessary. But the problems of contraception are only part of marriage preparation which, besides considering matters of general health and eugenics, must concern itself with the state of the hymen, effective technique, and the removal of various fears and anxieties in one or both partners. These are the important things and they take time.

When Dr. Saklatvala says "because coitus is being practised for some aim short of its natural purpose" and that there are "psychological barriers to the full play of the instincts which, in the last analysis, will be a sufficient guide to the young couple" he is on more interesting ground. What is the "natural purpose" of coitus? In animals it is an instinctive process necessary to reproduction. Human beings, however, have minds and spirits, and so to them, in its highest development, coitus is something far more profound. It is a means of expressing mental and spiritual unity, as well as a means of continuing the race. Both have equal importance in marriage. It is extremely important to make sure that there is a true release of emotional tension, and it is because this is so rarely achieved that so much disharmony develops later on. To my mind, the "psychological barriers" to which he

refers are precisely these anxieties and fears which must be removed before full emotional relief is obtained. The instincts by themselves are not "sufficient guide to the young couple. They must learn how to use them properly. This takes time, varying from a week to six months and it is essential to achieve this before the first pregnancy is well established. I agree, of course, that a couple should prove their fertility early, but if they have established a real emotional rhythm early they will have something valuable to return to twelve months later, and the women are not 'put off' or 'frigid'.

The way in which we handle these matters is the crux of the whole thing. It is because so many doctors will not accept these facts or deal with them so unsatisfactorily that the troubles arise to which Dr Wrathall Rowe (May 6 p 636) draws attention—namely, that people will not ask doctors about their sex problems. I hardly ever address a meeting of young people at which I am not asked "What is the use of advising us to go to doctors if the doctors will not help us?" They have tried so often and been given such poor or unsympathetic advice that they naturally go elsewhere. This is hardly to be wondered at when we realize that the problems of sex and marriage are scarcely touched upon in our medical schools. Is it not time that we put our house in order and concerned ourselves with the prevention of disharmony and frustration? This can only be done by a consideration of the practical and the psychological. If the problem is important before marriage it is even more so after the birth of the first child, when so many difficulties need adjustment, especially in the sexual sphere.

Dr Rowe is right when he draws attention to sex education, because it is here that we have an opportunity for really constructive work. The teaching of facts—the giving of sex instruction—however, is not enough. The education must be progressive and the parents must be encouraged to help. It must start in the home and proceed by gradual stages from factual information to a consideration of emotional development and end with the presentation of certain principles of sexual behaviour designed to help the individual in his personal life and also in the wider sphere of citizenship. Its purpose must be directed towards the strengthening of the family unit. Here is a field of work which the profession should enter more fully. Now that the authorities and especially the Board of Education, have given encouragement to the work we should seize the opportunity of putting across some really constructive information. I know from personal experience that such efforts are welcomed by young people provided the teaching is adequate and unemotional. Dr Blackett Jeffries (May 27, p 730) sums up the situation admirably when she says that knowledge does not ruin romance in marriage any more than does the study of technique spoil the artistic joy in self-expression. I would merely add that it enhances it.

Can we not begin to visualize the family as an entity and treat it as such? Friction between husband and wife, often having its origin in sex maladjustment, frequently transfers itself to the children and stimulates discord and delinquency. If we paid more attention to reconciliation we should not have to give out so many bottles of medicine to so-called neurotics—I am etc.

London W 1

EDWARD F. GRIFFITH

Migraine simulating Appendicitis

SIR—During the past few months I have seen two patients who complained of symptoms which clearly indicated that they were suffering from migraine. Both, peculiarly enough, had had their appendices removed at some time or other. On careful inquiry into their previous history I am convinced that both were suffering from early attacks of migraine when they were diagnosed as appendicitis and the organ in question removed. I have heard of attacks of migraine starting after appendicectomy, but have not heard or read of early migraine simulating appendicitis. The case histories are as follows.

A Male aged 29. About 9 months ago had an attack of lassitude, nausea, abdominal discomfort, constipation and dull headache. Next day he had several attacks of vomiting. Symptoms cleared up in about 24 hours. A few weeks later a similar attack occurred, and on abdominal palpation by his doctor he stated that he was slightly tender all over and more so in his right side. He was operated on a few hours later and his appendix removed. No clue to the findings

could be obtained. Since then similar attacks have occurred at intervals with headaches becoming more pronounced.

B Male aged 47. Gave a very similar history to Case A. He had his appendix removed some 20 years previously, and stated this was done after either one or two attacks identical with those from which he still suffers at intervals and which are undoubtedly migrainous.

It would seem quite easy to mistake an early stage of migraine for an acute or subacute appendicitis. The headache which was evidently not the patient's chief complaint before operation, was presumably due to the constipation from which he was suffering. The slight or marked abdominal tenderness could be explained by the repeated attacks of vomiting—I am, etc.

F L C R A F A R

Heat Hyperpnea

SIR—Referring to the note by Dr F R W K Allen in the *Journal* of Jan 22 1944—"Resuscitation by Rocking for Heat-stroke"—I would like to refer to an abbreviated article you kindly published for me on June 12, 1920. In this article the procedure as suggested by me was carried out in all cases treated by our unit during the campaign in Mesopotamia, 1916. There were no fatal cases so treated.

In heat hyperpnea the respiratory centre is seriously affected. If this centre cannot be made to function then the patient will die—irrespective of whatever other treatment is carried out. The utmost speed is essential in this treatment. Briefly, it was this:

Strichnine 1/60-1/15 gr was injected hypodermically immediately. This was given to start the functioning of the respiratory centre, and so indirectly keep the heart going. Immediately after this Schafer's method of artificial respiration was carried out. This was not stopped until the patient vomited. This symptom was invariably the sign of recovery. External lavage of the patient was then carried out—the patient resting on a stretcher across a trench—and river water poured on him so that he eventually became half submerged. The temperature was taken in the rectum every minute and the lavage was not stopped until the temperature registered 101° and remained steady at this level. After treatment consisted of wrapping the patient up in a calico sheet and keeping this wet until he was evacuated to a suitable hospital. Fruit juices and fluid diet in generous quantities were administered.

I have again mentioned this treatment in the hope that it may be of some use in tropical warfare—I am, etc.

Kingston Jamaica

JOHN N. MCINTOSH
Capt R A M C (ret)

"Merely Dyspepsia"

SIR,—For fairly obvious reasons there appears to have been a noticeable increase in abdominal cases since the beginning of the present conflict. Particularly do I refer to the "indigestion" with mild intermittent symptoms, which may seem so little and may mean so much.

Provided patients will seek medical advice in time I do not think the necessity for radiological examination can be too strongly emphasized for all patients of from early middle age onwards whose abdominal symptoms do not clear up within a month. Only so can the possibility of early malignancy be excluded and every such case must be considered "guilty" until it is proved "innocent." It is here that a great responsibility devolves upon the general practitioner who first sees the patient. No "label" must be attached to these symptoms, which, if not a cover for ignorance, indicates, what is worse still, a want of thoroughness. It is only to be regretted that so many patients strive to find a temporary relief in certain well advertised trade preparations, until the time for surgical intervention is past for ever—I am, etc.

Romford

W. DAVAN NEILL

F Ellinger and H Landsman *N Y St J Med* 1944 44, 2-9) state that among 1,280 cases of diabetes 39 cases of malignant growths were found. This cancer incidence of 3.04% agrees with a cancer incidence of 2.95% among 14,342 cases of diabetes collected from the literature. Since the cancer incidence in the State of New York was 0.46%, this means a decidedly higher cancer incidence in diabetes. As in previous observations a more virulent course of malignant growth was found with increasing severity of the diabetic condition.

Obituary

HUGH THURSFIELD, D.M.

Dr. W. P. S. BRANSON sends the following personal tribute:

Hugh Thursfield is dead, and many of us old-timers will be conscious of the chill that marks the passage of a warm and friendly spirit from its accustomed place. "Pobo," to use the queer nickname which came with him from Oxford to St. Bartholomew's and remained with him thereafter, was unusually equipped. Having already taken a degree in classics before he turned to medicine, he was a good deal older than his time. Thus he was able to diffuse something of his greater maturity and culture into the frequent arguments by which we youngsters sought to put the world to rights forty years ago. In those days, when political temperatures ran higher than they do now, and Radicals and Tories could be told apart, he was a Radical, while others of us were not. So it can be imagined how massive, and often indignant, were the contributions to the country's betterment which we wasted upon the seagulls along the Embankment as we walked home from Bart's of a Saturday afternoon. For Pobo was outright, even to abruptness, and sincere in all he said or did: with one playful exception, when he would trail his coat in order to provoke a friendly adversary.

Things went hardly for him in the way of promotion at Bartholomew's, for, being already older than others of his year, he fell victim to a spell of long stagnation in staff movements there, and thus remained far too long (for his great deserts) in subordinate teaching offices. Yet he never grumbled, nor thought meanly of the humdrum tasks that fell to him at that time, but held on, patiently keen, and thorough, and good-tempered. Indeed he was a grand fellow to know, and to have known: a man who could read the *Odyssey* through in the original once a year and thought it the "finest story in the world"; who was a good judge of claret, and for many years the moving spirit of the quarterly dinners of the Fellows' Club of the Royal College of Physicians; who was one of London's select company of bird-watchers and a regular visitor to the varsity rugby match. Humane, hospitable, companionable, and generous, he loved everything of good report, especially "laughter and good company"; and the long record of his paediatric and other writings bears witness to his ceaseless diligence.

Mr. W. McADAM ECCLES writes:

In the excellent review of Dr. Thursfield's medical career there is one fact which does not come out clearly. Thursfield commenced his medical studies at a somewhat later age than is usual. He qualified in 1897, being 28 years old. He was elected assistant physician to St. Bartholomew's in May, 1913. By that time the retiring age for the medical staff had been reduced from 65 to 60. In 1928, when it was seen that he had no chance of being a full member of the staff, he was on July 26, 1928, by special decree, promoted to be a full physician, finally retiring on July 31, 1929, when he reached 60. Apparently these circumstances are unique in the history of the ancient hospital.

Clun and district have suffered a serious loss by the death on May 17 of Dr. HAROLD ROBERT CROSS at the age of 70. His vigour of mind and body was maintained until a few months of his decease. He was a product of the Leeds General Infirmary, qualifying in 1899, and specialized in lunacy. After serving at the Clayton and then the Wakefield Mental Hospitals he was for 19 years senior medical officer at Storches Hall. A correspondent writes: Dr. Cross's 23 years' work at Clun in Shropshire will remain a loving tradition. He was there, incidentally, attached to Holy Trinity and St. Katherine's Hospitals. Outside his medical work, which he dearly loved, he threw himself whole-heartedly into the life of the community. He was ever a student and had the gift of an encyclopaedic mind.

Dr. DOUGLAS VERCORRE HAIG, who died on May 27 at Middleton St. George, Co. Durham, was born at Ahmednagar, Bombay, in 1873. He was educated at Bedford Modern School and Merchiston Castle School, Edinburgh, and at the University of Aberdeen, where he graduated M.B., C.M. in 1895 and took the M.D. in 1901. After house appointments at the Royal Aberdeen Hospital for Sick Children and the Cotswold Sanatorium for Consumption he was honorary anaesthetist to the Darlington Hospital for 10 years, and later, for a short time, honorary assistant surgeon. Before the last war he had had 6 years' service in the Territorial Force, and in 1915 went to France and afterwards to Belgium and Germany as major, R.A.M.C.(T.F.). Dr. Haig joined the B.M.A. in 1901 and

served as representative of his Division at the Annual Meetings in Liverpool, 1912, and Aberdeen, 1914. Up to the time of his death he was medical officer to Messrs. Pease and Partners, Ltd., Darlington.

Dr. MARK LOUIS MILLER THOMSON, who died at Hoddesdon, Herts, on May 31, had been in practice there for the past twelve years and had an established position both as a general practitioner and as a citizen. Born at Steppes, Scotland, in 1901, he graduated M.B., Ch.B. of Glasgow University in 1923. He was first in practice as an assistant at Shipley, Yorks, and later at Pelaw, Newcastle-upon-Tyne. In Hertfordshire he found the type of practice which seemed to him ideal, giving plenty of scope for a wide range of medical activities and enabling him to take an active interest in his patients and in the affairs of the community. He was for some time a member of the local Urban District Council and was instrumental in setting up a public library, which has been very much appreciated by the people of Hoddesdon. His practice steadily increased, and at the time of his death he was, without question, one of that group of general practitioners to whom the term "family doctor" particularly applies and to whom it meant a vital concern for every sick person under his care. His cheerfulness and charm were appreciated in every home in the district. This and his wide interest in the present and future position of the medical services were also appreciated by his medical colleagues, and he had recently been elected deputy chairman of the East Hertfordshire Division of the B.M.A. Dr. Thomson had had no illness of any kind, and his very sudden death at such an early age has robbed Hertfordshire of one whose devotion to medicine and determination to keep abreast of modern developments must be a great loss. He leaves a widow, Dr. E. M. Thomson, who is continuing in the practice, and three children. His attitude to medicine is perhaps best reflected in the fact that his two sons are already determined to follow him in the medical profession.

Dr. GEORGE BERTRAM BARTLETT, formerly professor of pathology in Capetown University, died on June 3 at Dorchester. He was born near Blandford on April 9, 1880, the second son of Arthur Bartlett of Wimborne, and from Weymouth College went to Sydney Sussex College, Cambridge, where he graduated B.A. in the Natural Sciences Tripos of 1902. His clinical course was taken at the London Hospital, and two years after qualifying in 1906 he was appointed assistant director of the Pathological Institute there and in 1912 lecturer on pathological histology in the medical college. During the last war Dr. Bartlett served first with an infantry regiment and then joined the R.A.M.C., working as pathologist to No. 21 General Hospital, Alexandria, and to No. 27 General Hospital, Cairo. Between these two appointments he was posted for some months to the malaria laboratory of the 4th London General Hospital. In 1920 he went to take up the vacant chair of pathology at Capetown University, where he remained until 1924. After retiring from active work he lived at Hove, and spent much time in open-air pursuits.

Dr. HERBERT MARTIN BERRY, well known as a radiologist, died on June 3 at Staines, aged 65. A student of University College, Liverpool, he graduated M.B., Ch.B. of Victoria University in 1902, and took the M.D. of Liverpool University in 1914 and the D.M.R.E.Camb. in 1921. Martin Berry was a pioneer medical worker with x rays. In the 'nineties he left general practice in Staffordshire to specialize in radiology in London, and he was for some years chief assistant in the x-ray department of St. Bartholomew's Hospital under Hugh Walsham. During the last war he served as captain, R.A.M.C., at the Herbert Hospital, Woolwich. After returning to civil life he held appointments as radiologist to a number of hospitals in and around London, including the Hospital for Women, Soho Square, the Dreadnought Hospital, the Mount Vernon Hospital, and the Waterloo Hospital for Women. He had joined the B.M.A. in 1912 and was a member of the Roentgen Society and the British Association for Radiology and Physiotherapy.

A veteran member of the profession in Scotland, Dr. DAVID HUSKIE, of Moffat, Dumfriesshire, died on June 7 in his 81st year. He was educated at Dollar Academy and at Edinburgh University, where he captained the University rugby XV. He graduated M.A. in 1884, M.B., C.M. in 1888, and was elected F.R.C.P.Ed. in 1926. Dr. Huskie took a keen interest in local affairs and was provost of the borough of Moffat from 1911 to 1929. He was chairman of the trustees of Moffat Cottage Hospital, and it was largely due to his efforts that the hospital was built. He was an honorary life member of the St. Andrew Ambulance Association and a J.P. for Dumfriesshire. He

joined the B.M.A. as long ago as 1890 was a past president of the Border Counties Branch, and served for ten years before this war on the Insurance Acts Subcommittee for Scotland. He retired in 1940 after 50 years in active practice.

Dr GEORGE BLACKER MORGAN, who died on June 8, aged 80, was honorary physician to the Sunderland Royal Infirmary from 1905 to 1923, when he was made consulting physician. The son of Dr G. B. Morgan J.P., he was born at Sunderland on Dec. 1, 1863, and was educated at Ayscough and Repton Schools and at Trinity College, Dublin, graduating B.A. Dub. in 1887, M.B. B.Ch., B.A.O. in 1889, and M.D. in 1907. He returned to Sunderland in 1889 as house surgeon to the Royal Infirmary, and after his appointment to the visiting staff became consulting surgeon to the Sunderland Maternity Home and medical adviser to the Durham Coal Owners' Association. During the last war he served as medical officer to the Sunderland War Hospital. He took a warm interest in the local reformatory and industrial schools, for which he acted as honorary medical consultant.

Dr WILLIAM NORMAN MAY, who died on June 12, aged 62, after an operation at Reading, graduated M.B. B.S. Lond. from Guy's Hospital in 1904 and took his M.D. in 1906. After house appointments at Guy's he was resident medical officer to the East London Hospital for Children, Shadwell. He held a commission as temporary captain R.A.M.C. in the last war, afterwards he made his home at Sonning-on-Thames and was appointed honorary physician and physician-in-charge of the skin department of the Royal Berks Hospital, Reading, and specialist in tropical diseases for the Reading area under the Ministry of Pensions. Dr May joined the B.M.A. in 1909 and was a past president of the Reading Pathological Society. A keen student of bird life, he was a member of the British Ornithological Union and Club.

The death occurred in Capetown on June 15 of Dr CHARLES ARTHUR WILSON RAMSAY, a well known medical practitioner in Salisbury, Southern Rhodesia, for more than twenty years. He was born in Belfast in 1894 and took the degrees of M.B. B.Ch., B.A.O. at Queen's University. After serving with the R.A.M.C. in the last war he went to the Colony in 1920 and settled at Salisbury. Dr Ramsay was honorary consulting physician to the children's ward of the Salisbury General Hospital and for two years president of the Mashonaland Branch of the British Medical Association. A keen golfer, he won the Royal Salisbury Club Championship in 1941.

Dr LEWIS JOHNSTONE WEATHERBE, who died in retirement at Workop on June 15, had been medical officer to the Rotherham Rural District Council for 38 years. Born at Halifax, Nova Scotia, on Feb. 16, 1867, son of S. F. Robert Weatherbe, he was educated at Edinburgh University, graduating M.B. C.M. in 1890. During the South African War he served with Paget's Horse and in the war of 1914-18 he held a commission in the R.A.M.C. for two years. In 1920 Dr Weatherbe gave up private practice and devoted the whole of his time to the work of M.O.H. which he relinquished on grounds of health in 1935. During his long association with the Rotherham R.D.C. the district developed from a truly rural area and he was responsible for introducing many measures for the benefit of the inhabitants.

Mr SAMUEL WILFRID DAW, who died on June 19 at Polegate, Sussex, where he had been living in retirement, was formerly orthopaedic surgeon to the General Infirmary at Leeds and consultant in orthopaedics to the Leeds Education Committee and Public Health Department. He qualified from Guy's Hospital in 1906 taking the English Conjoint diplomas and the M.B. B.S. degrees of London University. Two years later he obtained the F.R.C.S. After serving as resident surgical officer at Guy's he held the corresponding post at the Leeds General Infirmary and later became surgical registrar there and surgical tutor in the University. Besides his work at Leeds Mr Daw was also consulting orthopaedic surgeon to the Batley Hospital, the Claxton Hospital, the Wakefield and Dewsbury Infirmary, and surgeon to the Kirbymoorside Orthopaedic Hospital. He was a Fellow of the Association of Surgeons and a member of the British Orthopaedic Association. At the Annual Meeting of the B.M.A. at Nottingham in 1926 he held office as vice president of the Section of Orthopaedics.

We regret to announce the death at the age of 47 of Dr ARTHUR JOHN SMYTH, medical officer of health and school medical officer for the borough of Cambridge and superintendent of the infectious diseases hospital. Dr Smyth had his medical training at Cambridge University and St. George's Hospital, qualifying M.R.C.S., L.R.C.P. in 1923. He graduated

B.Ch. at Cambridge and took the D.P.H. two years later and the M.B. degree in 1931. Before entering the Public Health Service as assistant M.O.H. for the Godalming district he had been house-physician to the Victoria Hospital for Children, Chelsea, and house surgeon, house physician, and casualty officer at St. George's Hospital. He joined the B.M.A. in 1926 and was elected chairman of the Cambs and Hunts Division a year ago.

The tragic death through enemy action of Dr JAMES FETTES and his wife came as a terrible shock to his many friends. J. H. writes: "I have known James Fettes intimately for many years and he became a real friend of my family. He had that cheerful happy disposition which endeared him to his patients and to all who met him. He was a sound clinician, an extremely hard worker, and was deeply interested in the future of medicine and the welfare of his medical colleagues. As chairman of the City Division of the B.M.A. he did sterling work in upholding the high ethics of the profession. His cheerfulness, ready wit, and unfailing kindness will be sadly missed."

News has reached this country of the death on April 9, at a tea estate in Dooars, Bengal, of Dr BURGESS BARNETT whose name became well known some years ago through his work on the medical use of snake venom. He was born at Camberwell on April 10, 1888, and from Marlborough College went to St. Bartholomew's, qualifying M.R.C.S., L.R.C.P. in 1915. After serving as house physician at Bart's he was a temporary captain in the R.A.M.C. for two years and then practised in the Lobitos oilfields of Peru where he made a special study of snakes. In 1932 the Council of the Zoological Society of London appointed him curator of reptiles, after holding this post for five years he resigned it to devote his time to further research on snake venom and its application in medicine. In 1938 he was appointed superintendent of the Zoological Gardens at Rangoon, where a new reptile house was being built and a snake farm for the collection of venom. He wrote the article on snake-bite for the *Index of Treatment* in 1940 and published several papers on the haemostatic uses of snake venom. In May, 1943, Barnett was awarded the M.B.E. for bravery in Burma, when as principal medical officer of the Burma-China railway construction he stayed behind with refugees during the evacuation through the Chankam Pass and tended them on a long and perilous march.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated

FINAL M.B.—Part II (Principles and Practice of Physic Pathology and Pharmacology): T. S. L. Bewick, R. H. Boardman, D. G. Bratherton, D. Brazier, A. Comfort, G. S. Crockett, P. B. Davies, P. J. Deane, J. A. Dunder, D. A. W. Edwards, M. A. Floyer, P. H. Friedlander, J. W. Fullerton, C. R. H. Green, J. A. Harrington, C. E. Hardie, S. M. Hifton, R. F. Hollick, N. S. Hoo, W. R. Horsfall, G. I. C. Ine, R. E. Irvine, J. Lorber, M. B. Matthews, J. R. May, J. M. Morgan, M. Newton, K. N. V. Palmer, P. B. Philip-Smith, D. A. Pond, P. D. G. Pugh, G. F. Roberts, J. Roche, B. S. Hofield, J. A. Shiers, J. F. N. S. Debotham, C. A. S. Orr, J. M. Stowers, M. Smiers, R. G. Turner, D. R. D. Vanstone, B. H. Vawter, D. G. Vester, P. Venables, S. M. Vine, P. R. Westall, A. P. Wignall, L. Wolman, G. S. Yeoh, W. R. R. C. A. Hutter, R. S. M. Chon, M. M. Turnbull, Behrens.

UNIVERSITY OF LONDON

LONDON HOSPITAL MEDICAL COLLEGE

Essays for the Liddle Triennial Prize, value £120 must reach the Dean of the London Hospital Medical College, Turner Street, E.1, not later than July 31, 1946. The prize is open to public competition and the subject for the next award is "Epidemic Jaundice." A statement of the conditions may be had on application to the Dean.

UNIVERSITY OF EDINBURGH

At the last meeting of the University Court intimation was made of a bequest for the establishment of a bursary, to be awarded each year to the medical student of the university who has within the year passed the third professional examination and has obtained the highest total aggregate of marks in the first, second, and third professional examinations. For this purpose the late Miss Margaret Campbell Surton left a share of the residue of her estate, the bursary to be named in memory of her father, the late James Surton, M.D. The amount of the bequest is estimated at about £2,500. The Court, in accepting the endowment, remitted to the Faculty of Medicine to prepare regulations for the award.

The Services

Temp. Surg. Lieut. R. C. P. Aldridge, R.N.V.R., has been mentioned in dispatches for coolness and energy in dealing with the injured when a hospital ship was hit by a bomb and all the other medical officers were wounded.

Cpts. (Temp. Majors) E. F. Claridge and V. J. Downie, and Cpts. J. H. Brown, E. J. D'Arcy, G. E. David, W. Lamb, C. J. Mill-Irving, G. E. Pinkerton, and E. G. Turner, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Italy.

CASUALTIES IN THE MEDICAL SERVICES

Wounded.—War Subs. Cpts. N. H. H. Gollidge and W. Lamb, and Lieuts. C. R. Forrest and T. Notman, R.A.M.C.

Missing.—Capt. W. E. Church, R.A.M.C.

Missing, presumed killed on active service.—Surg. Lieut. G. S. Davis, R.N.V.R.

Medical Notes in Parliament

Medical Research

On June 20 Mr. SALT asked the Lord President of the Council whether any plans were under consideration for expanding the research programme of the Medical Research Council in regard to medicine and all related fields as soon as circumstances and available personnel allowed, and whether he was satisfied that it had, or would have, sufficient funds available for the purpose.

Mr. ATTLEE replied that various plans were under consideration, and the Medical Research Council had already been able to initiate certain new schemes with a view to development as soon as circumstances permitted. Among other things, they had recently established a research unit in applied psychology at Cambridge; and research units in industrial medicine, human nutrition, and otology in London. The new building for the National Institute for Medical Research, completion of which had been interrupted by the war, would also make it possible to expand the Council's central establishment. The Government had already stated its intention of giving full support to research work.

Army Casualties

On June 27 Mr. CHURCHILL, replying to Dr. Elliot, said that on February 16 he informed the House that up to February 12 the following casualties had been sustained by the British in Italy, including Dominion and Indian troops: killed, 35; wounded, 23,283; missing, 5,708—total, 36,626. Between that date and the entry into Rome these Forces sustained the following further casualties: killed, 6,696; wounded 24,683; missing, 5,117—total, 36,496. Our total casualties, therefore, from our landing in Italy to the fall of Rome were: killed, 4,331; wounded, 47,966; missing, 10,825—total, 73,122.

These figures were for Army casualties only, Navy and Air Force losses being excluded. This was the basis on which the earlier figures were given in February, it having been found impossible to give a figure for the other two Services exclusively relating to operations in Italy as distinct from the other operations of the Navy in the Mediterranean and of the Air Force over the Mediterranean, Germany, Central and Eastern Europe, and the Balkans.

Aid for Scientific Research

Prof. HILL asked the Lord President of the Council to which of the three bodies under his direction—the Department of Scientific and Industrial Research, the Medical Research Council, and the Agricultural Research Council—applications should be directed for financial assistance to research on genetics, cytology, vital statistics, biophysics, general physiology, and experimental psychology. Mr. ATTLEE said that where there was no indication to the contrary in a particular case it would be appropriate to address applications in the first instance to the Medical Research Council if they related to human genetics, vital statistics, biophysics, general physiology, or experimental psychology. The Department of Scientific and Industrial Research, the Medical Research Council, and the Agricultural Research Council aided specific projects for fundamental research when further knowledge was required in the fields for which they were responsible, even if it could be shown that

such researches had an immediate application to industry, medicine, or agriculture.

Hospital Treatment of Normandy Casualties

Mr. ARTHUR HENDERSON announced on June 29 that for the time being casualties from Normandy would have to be treated in the hospitals which could be most conveniently reached from the port of disembarkation. As soon as circumstances permitted, wounded men would once more be sent to suitable hospitals as near their homes as possible. Patients requiring treatment in specialized hospitals would continue as before to be sent to those hospitals wherever they were located.

Health Division of UNRRA

Mr. GEORGE HALL, in reply to Capt. Plugge on June 28, said that the divisions of UNRRA which dealt with health, nutrition, agriculture, and other relevant matters had been placed under directors and deputy directors appointed for scientific or technical qualifications and experience. Recruitment and organization of the staff both in London and Washington were still in progress. Instances illustrative of the qualifications and experience of the scientific staff generally were:

Health Division, Washington. Director, Dr. W. A. Sawyer, formerly Director of the International Health Division of the Rockefeller Foundation.

Health Division, London. Director, Dr. A. Topping, formerly Deputy Medical Officer of Health to the L.C.C.; Deputy Director, Dr. Neville Goodman, formerly Deputy Senior Medical Officer, Ministry of Health.

Medical Auxiliaries in an N.H.S.—In reply on June 29 to Sir Ian Fraser, Mr. WILLINK said the aid of masseurs and physiotherapists would be required in the new comprehensive service. The total demand on their services was thus likely to be considerably increased. Whether private practice in these specialties would be diminished he could not say, but there would be no interference with the right to give or receive private treatment.

The Nursing Situation.—Answering Mr. Sorensen on June 22 Mr. WILLINK said the strain upon nurses working in hospitals was in many cases severe. While the shortage of nurses had hitherto prevented many hospital authorities from reducing working hours to the level generally considered to be desirable, there had recently been a substantial improvement in the staffing position. He understood that 3,200 more nurses were employed in hospitals and similar institutions on April 16, 1944, than at January 1, 1944. Nursing work enjoyed the highest possible priority. Any girl who desired to become a nurse was, with negligible exceptions, given permission to enter upon the work. Women with previous nursing experience were freely released to return to the profession. Steps were taken to bring information about nurses to the notice of suitable women and the need for additional nurses was impressed on them. This need was also made known to school-girls.

Medical Education.—Mr. WILLINK said on June 22 that the arrangements for the future training of medical students have been fully reviewed by Sir William Goodenough's Committee on Medical Schools, and the committee's recommendations will shortly be published.

Notes in Brief

The Statute Law Revision Committee has listed, among the subjects suitable for its consideration, dangerous drugs, lunacy, and the unconsolidated part of the Pharmacy and Poisons Acts.

On June 20 Major Lloyd George informed Mr. S. Davies that he had received the report from the Pneumoconiosis Advisory Committee which he set up last year. The report would be made available to the public.

The following have been appointed Honorary Physicians to the King for a period of three years: Andrew Davidson, M.D., Chief Medical Officer, Department of Health for Scotland; E. R. A. Merewether, M.D., Senior Medical Inspector, Factory and Welfare Department, Ministry of Labour and National Service; Prof. G. Selby Wilson, M.D., F.R.C.P., Professor of Bacteriology, London School of Hygiene and Tropical Medicine, and Director of the Emergency Public Health Laboratory Service; W. R. Thomas, M.D., F.R.C.P., Senior Commissioner, Board of Control; J. A. Charles, M.D., F.R.C.P., Deputy Chief Medical Officer, Ministry of Health (until recently Medical Officer of Health, Newcastle-upon-Tyne); H. M. C. Macaulay, M.D., Medical Officer of Health, Middlesex County Council. The following have now completed their term of office as Honorary Physicians to the King: Sir Henry Bashford, M.D., F.R.C.P., Medical Adviser to the Treasury; Sir Weldon Dalrymple-Champneys, Bt., D.M., F.R.C.P., Deputy Chief Medical Officer, Ministry of Health; R. Veitch Clark, M.B., lately Medical Officer of Health, Manchester; W. G. Clark, M.B., Medical Officer of Health, Edinburgh; James Ferguson, M.B., Medical Officer of Health, Surrey County Council.

No. 24

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 17.

Figures of Principal Notifiable Diseases for the week and 13 weeks for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded within each infectious case, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

± Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales notifications of measles dropped by 455, and those of acute pneumonia by 248, but those for whooping-cough and scarlet fever went up by 155 and 116 respectively.

Diphtheria notifications continued to fall, there being 14 fewer cases recorded than last week's low total. The only increase of any size in the incidence of scarlet fever occurred in Essex, where the total was 31 higher than last week. Acute pneumonia was less prevalent throughout the country. Whooping-cough had a slightly higher incidence in most areas, especially in the south-east, where last week's total was exceeded by 98; in the south-west notifications fell by 65. Lancashire reported 140 fewer cases of measles than last week, Wiltshire 71, and Kent 59. In Northumberland, however, notifications went up by 58.

There were 10 more cases of dysentery reported than last week. The chief centres of infection were Lancashire 35, London 28, Derbyshire 17, Kent 14, Gloucestershire 11.

In Scotland the total diphtheria notifications fell by 52, the number of cases reported being the smallest during recent months. Dysentery continued to decline, over half the total cases occurring in three areas: Glasgow 16, Edinburgh 10, Stirling County 10. The rise of 41 in the total notifications of whooping-cough was contributed mainly by Glasgow.

In Eire measles notifications fell by 45, but diphtheria was still prevalent, 35 of the 82 cases being notified in Dublin C.B.

Quarterly Returns for Eire

The birth rate during the March quarter was 22.7 per 1,000, this being 0.6 above that for the corresponding quarter of last year. Infant mortality was high—101 per 1,000 births. The general death rate was 20.1 per 1,000—3.0 above the rate for the first quarter of 1943. Deaths from pulmonary tuberculosis were 852, and from other forms 242, the former being 107 fewer, and the latter 18 more, than in the first quarter of 1943. There were 521 deaths from the principal infectious diseases, almost 200 more than the average of the five preceding first quarters; 287 deaths were due to diarrhoea and enteritis under 2 years of age, compared with an average of 169.

Week Ending June 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,451, whooping-cough 2,424, diphtheria 487, measles 2,538, acute pneumonia 452, cerebrospinal fever 53, dysentery 201, paratyphoid 7, typhoid 10.

Medical News

Mr. Desmond MacCarthy's Lloyd Roberts Lecture, announced for July 11 at the Royal College of Physicians of London, has been postponed.

The three lectures on colloid science by Prof. E. K. Rideal, F.R.S., announced on June 17 (p. 831) have been postponed.

At a meeting of the Clinical Society of the Royal Eye Hospital to be held at the hospital (St. George's Circus, Southwark, S.E.) on Friday, July 28, at 5.30 p.m., Dr. D. G. Ardley will speak on sulphamide therapy.

At the annual general meeting of Epsom College held on June 16 Lord Leverhulme, the president, stated that at the end of the year under review the deficit of £1,500 had been entirely cleared off and there was a surplus of £1,780, a proof that the co-operation between the Council, the staff, and the boys must have continued with good effect. For the first time since 1939 the school account showed a credit balance of £700, which must prove of great help in view of the heavy expenditure that would be necessary for repairs after the war. The College as a medical foundation could not complain that both medicine and education had had a very full share of the political limelight during the past twelve months.

The Save the Children Fund has received news of the arrival in the Middle East of its third foreign relief team which, under the direction of UNRRA, is available for working in the liberated territories. This team is led by Dr. Katherine S. Macphail, medical superintendent of the Anglo-Yugoslav Children's Hospital in Yugoslavia, who has been attached to the Save the Children Fund for more than twenty years past. Dr. A. B. Howitt, M.P., chairman of the Parliamentary Medical Committee, has accepted an invitation to serve as an honorary medical adviser to the Save the Children Fund, and the British Paediatric Association has also promised to assist the fund in a similar capacity. These appointments are in addition to the existing hon. medical advisers, Dame Louise McIlroy, Dr. Matthew B. Ray, and Dr. Leslie Housden.

The annual general meeting of the British Empire Leprosy Relief Association was held at the India Office on June 29 under the chairmanship of the Right Hon. Oliver Stanley, Secretary of State for the Colonies. Sir William Peel, chairman of the executive committee, in an address reporting on the work of the Association during the year 1943, said that war conditions made it impossible to embark on any new schemes, but the work in hand had been well maintained, with some expansion along existing lines. The medical secretary, Dr. Ernest Muir, continued in charge of the Chacachacare leper settlement in Trinidad, having been lent to that Colony for the period of the war, and he had paid visits to British Guiana and Jamaica. The Association was indebted to Sir Leonard Rogers for carrying out Dr. Muir's duties at home in an honorary capacity and for continuing to edit the *Leprosy Review*. The committee much regretted the resignation on health grounds of Sir Frank Carter from the post of honorary treasurer; he had been a supporter of the Association since its inception over twenty years ago. Sir Leonard Rogers addressed the meeting on medical aspects of the leprosy problem.

At a meeting of the Executive Committee of the Scottish National Blood Transfusion Association held in Edinburgh it was stated that the number of enrolled blood donors throughout Scotland had increased by over 13,000 during the year to March 31, 1944. The extension of the mobile bleeding teams, each consisting of a medical officer and technical and nursing assistant, had proved highly successful. These teams, in specially equipped cars, had visited many outlying areas and had attended at hundreds of factories throughout Scotland for the purpose of testing and bleeding donors with the minimum of inconvenience to their work. It was reported that the plant installed for the preparation of dried plasma had operated very successfully, and the storage of dried plasma had proved of great advantage in meeting sudden demands and in acting as a reserve for the Armed Forces, the Merchant Navy, and for civilian needs.

Mr. A. B. Inglis, Dr. C. H. Kellaway, F.R.S., Messrs. L. G. Matthews and J. Russell, have been elected directors of the Wellcome Foundation Ltd. Dr. Thomas Dewar has been appointed secretary.

Lord Hailey has been elected president of the Research Defence Society. Prof. A. V. Hill is still chairman of committee, and Sir Leonard Rogers continues as hon. treasurer and acting hon. secretary.

Dr. T. V. Crichlow, D.M.R.E., assistant radiologist to the Middlesex Hospital, has been appointed radiologist to the British Legion Village, Preston Hall, Maidstone.

A mass radiography service to facilitate the early diagnosis of tuberculosis was officially inaugurated at St. James's Hospital, Leeds, on July 3. This unit will make possible the examination of between 1,000 and 1,500 persons a week, and it is proposed to take it to large works and schools, as well as to operate it at the hospital.

The British Pharmacopoeia Commission announces that the requirement for iodine value of glycerides in oleum hippoglossi, halibut-liver oil, Fourth Addendum to the *British Pharmacopoeia*, 1932, 23, is changed from "112 to 130" to "112 to 150."

1. Director of Health for the European Region of UNRRA, Andrew Topping, has invited representative members of the nursing profession to assist him in the consideration of problems arising from the demand for nurses for relief work in the liberated territories of Europe. A consultative committee has been set up to deal with questions of terms and conditions of service as well as with applications for employment as nurses with UNRRA. The committee has met twice and has selected the chief nursing officer and two district public health nursing officers for a mission over-seas. Further meetings will be held to consider vacancies in the public health nursing field as occupied countries are liberated and health missions are established.

The Royal College of Surgeons of England has acquired freehold property in Lincoln's Inn Fields, including premises that were until recently held by the College of Estate Management. The object of these purchases is to safeguard future development. To the east of the present building the Royal College of Surgeons now owns the vacant sites of Nos. 35, 36, and 37, and it also owns No. 38, which is still standing. To the west it owns the freeholds of Nos. 44 and 45. In addition to the parts of the existing College which only need restoration there remain the parts of the original site which were occupied by buildings destroyed by enemy action. The old lecture theatre and two large museum halls originally occupied this space.

Mr. F. W. Gamble, Ph.C., vice-chairman and one of the managing directors of Allen and Hanburys Ltd., has, owing to prolonged and serious illness, tendered his resignation from the Board. Mr. Gamble's fellow directors have put on record their appreciation of his earnest and devoted work in the interests of the company and of pharmacy for close on 50 years.

Dr. Emil Feer, formerly professor of children's diseases at Zurich University, was 80 on March 5.

Letters, Notes, and Answers

ANY QUESTIONS?

Treatment of Calcium Deficiency

Q.—What is the latest method of treating a case of calcium deficiency characterized by fragility of the bones associated with at least one spontaneous fracture? Blood calcium is low—e.g., a report dated June, 1943, gives it as 8.5 mg. per 100 c.cm., and the accompanying x-ray report was gross calcium deficiency. Later reports say that the blood calcium is still low. The patient is a girl of 19, and the condition began about two years ago. There has been marked improvement under treatment with intramuscular calcium, vitamin D, and U.V. therapy. There is a history of abdominal tuberculosis in childhood, and presumably the difficulty in absorption of calcium is due to disorganization of the mesenteric glands. I have heard of a method in which alum acetate is given by mouth with the idea of precipitating phosphorus and allowing calcium to be absorbed.

A.—A little more information, especially about the amount of fat in the faeces, would make this question easier to answer. Assuming that the diagnosis is correct, treatment with calcium, vitamin D, and U.V.R. is quite correct, though there should be no need to give the calcium intramuscularly. The vitamin D will probably sufficiently increase the absorption from the intestine. Treatment with aluminium acetate was first suggested by A. J. Helfet in 1940 (*Brit. J. Surg.*, 1940, 27, 651). Helfet suggests that the function of the parathyroids is to control the level of inorganic phosphate in the blood, a rise in blood phosphate resulting in stimulation of the parathyroids and therefore, indirectly, in the removal of calcium from the bones. He gives 75 minims of the B.P. liquor of aluminium acetate a day. This combines with the phosphate in the intestine to form insoluble aluminium phosphate, thus lowering in turn the blood phosphate, the activity of the parathyroids, and the mobilization of bone calcium. Aluminium acetate is quite harmless even if given over long periods, and Helfet's results suggest that the method is worthy of trial. Helfet does not give extra calcium, but in the case described a continuation of a high calcium and high vitamin D intake is to be recommended.

Sulphonamides and Deafness

Q.—Is there any definite evidence for the suggestion that sulphonamides cause deafness in infants? If so, what are the prognosis and treatment (if any)?

A.—We are aware of no foundation for this suggestion, and indeed of no mention of it in medical literature. If such a belief has arisen, presumably in the lay mind rather than the professional, it may be accounted for by the fact that the sulphonamides are largely used in treating conditions which are themselves liable to be followed by deafness, such as middle-ear disease and cerebrospinal fever.

Mental Deficiency

Q.—I have as a patient a child of 9 years who has never been able to speak. She has no physical abnormality, although her mental capacity is, so far as I can see, somewhat subnormal. She tends to be aggressive, and her expressions are limited to such vague utterings as "bah." She is not deaf. Can you tell me what classification she falls into, and what the prognosis is?

A.—Deafness being excluded, by far the likeliest explanation is that the child is a low-grade mental defective. In that event the prognosis is hopeless, apart from making the best, by care and skillful training, of the patient's limited mental endowments. Such conditions as word-deafness, which might supply an alternative explanation, are extremely rare. A history of the child's development, together with a mental examination, should place the diagnosis beyond doubt. Thus, for example, at what age did she walk and when did she establish control over her sphincters? Can she look after herself, feed and dress herself, execute commands and carry out commands? When did she learn to do so? What is her performance, compared with the normal child of 9, on intelligence tests of a non-verbal character?

Amoebic Dysentery in a Child

Q.—I would be grateful for advice on the treatment of amoebic dysentery in a child 5½ years old who contracted this disease when 15 months old, and after treatment for several months was apparently cured with stovarsol capsules. I was called to see the child the other day, and examination of the stools showed a recurrence of the trouble. The child had been in the Gold Coast up till two years ago, when she arrived in this country.

A.—Amoebic dysentery is extremely rare in European children. Before treating the disease it is imperative that parasites be found and identified and the diagnosis confirmed. Neither stovarsol, the emetine preparations, nor any other drug alone will eradicate the infection. It is necessary to give a combination of drugs to this end, over a period of about three weeks, and for this purpose the child should enter hospital.

A Case of Congenital Syphilis

Q.—A girl of 22 was found to have interstitial keratitis 2½ years ago, and a positive Wassermann. She has had repeated courses of N.A.B. (total 4 g.) and bismuth, with mercury by mouth between. Her Wassermann is still positive and the Dreyer keeps about 1.0. (a) How long should the above treatment (if approved) be continued? (b) Can one hope to make the Wassermann negative, and if not, is she infectious, if she marries, to her husband, and to a child? Incidentally her father knew he had gonorrhoea but not syphilis, and both he and his wife have negative Wassermans and Dreyers.

A.—This appears to be, almost certainly, a case of congenital syphilis, in spite of the negative blood reactions of the father and mother. The first thing to do is to test the cerebrospinal fluid for Wassermann, cells, protein, and colloidal gold curve. Assuming these are negative, further treatment than that already given is indicated—a total of 4 g. of N.A.B. is a relatively small amount—and should extend over a period of at least two years; neoparsphenamine in weekly doses of 0.45 g. intravenously, and an insoluble preparation of bismuth in weekly doses of 0.2 g. of the metal intramuscularly, should be given concurrently in courses of 10 injections of each, with rest intervals of about three months between consecutive courses; a total of not fewer than 30 injections of arsenic and 40 of bismuth should be given; this includes treatment already administered. In addition, mercury in the form of colloidal mercury sulphide may be given during intervals between courses in doses of 5 c.cm. intramuscularly once a week. Vitamin E complex, combined with vitamin B complex (Stone, S., *Arch. Ophthalmol.*, Chicago, 1943, 30, 467), is said to be a valuable adjunct in treatment.

On the other hand, should the C.S.F. be positive, pentavalent arsenicals and some form of fever therapy are indicated. These should be given only by an expert. It is extremely unlikely that the serum reactions will be reversed to negative, but prolonged treatment is recommended, mainly with the object of preventing relapse. Assuming this is a case of congenital syphilis, the patient is not infectious, nor would she convey her disease to husband or child; third-generation syphilis is a very doubtful possibility, and in any case extraordinarily rare.

Sedatives for Injured Children

Q.—What is a safe and correct dose of morphine to give hypodermically to a child suffering from injuries, say, resulting from a road accident, and below what age is morphine in such cases unsafe? I have seen cases of young children who, in spite of fracture of both bones of the lower leg, struggle violently, flinging the injured limb about in the air like a flail and offering the most stubborn and screaming violence to any attempt at splinting or even quietening.

A.—Morphine gr. 1/75 for each year of the child's age may be regarded as a safe dose. While this applies to any age, tinct. opii minimis 2 for each year of the child's age is often more satisfactory than morphine, especially in infancy. In answer to the statement in the latter half of the question, it may be remarked that in the circumstances described a sedative would prove more valuable than an anodyne—say, syrup of chloral rather than morphine.

What is "Biotin"?

Q.—Is there such a thing as vitamin H? Is it true that it is essential to the growth of hair and its deficiency is responsible for premature baldness? If so, is vitamin H available in the market? How is it administered? What are its composition and origin?

A.—Vitamin H, now known as biotin, is a crystalline, water-soluble compound with the composition 2-keto-3:4-imidazolido-2-tetrahydrothiophene-n-valeric acid. It was synthesized last year in America by Harris. Biotin is a member of the vitamin B complex, and is therefore found in foodstuffs containing the latter, particularly liver, yeast, kidney, pancreas, adrenals, and cereals. Biotin is essential for the complete nutrition of many animals and possibly of

man, since Sydenstricker in America has produced a deficiency syndrome in volunteers on diets poor in biotin. The physiological function of biotin is unknown. Rats given diets deficient in biotin develop a scaly, greasy dermatitis and atrophy of the fur. This has given rise to the misconception that biotin is essential for the growth of human hair, and that its deficiency results in premature baldness. There is absolutely no evidence for this. The cause of human baldness is unknown, and neither biotin nor any other known vitamin can prevent or cure it.

Biotin is available commercially only in the U.S.A. It is extremely expensive, and our present knowledge of it does not warrant its use in any clinical condition. Clinical biotin deficiency is very unlikely, as biotin is widely distributed in foods. A deficiency can be produced artificially by feeding large quantities of raw egg-white—e.g., 200 g. of dried white daily. A case of biotin deficiency has been reported in an Italian who ate a large number of raw eggs a day and neglected his diet generally (see *Journal*, 1943, 2, 271). Raw eggs (not cooked) contain a principle known as avidin which inactivates biotin.

Artificial Insemination

Q.—(a) Do facilities exist in this country through any organization for the induction of artificial insemination, using an exogenous donor? (b) What prospects of success attend such a procedure, if indeed it has been put into practice in this country? (c) Where ejaculation cannot voluntarily be effected, has any other procedure, such as seminal vesicle aspiration of the husband, ever been attempted? My questions arise in the case of a childless marriage where both parties would welcome artificial insemination as an alternative to adoption.

A.—No facilities at present exist in this country for the obtaining of donated semen. When this is available, and a proper technique is adopted, artificial insemination gives excellent results. There is no means of obtaining semen otherwise than by ejaculation, and attempts to obtain it by aspiration are useless. In America there exist special fertility clinics where all the investigations and treatment of infertility, including insemination with donated semen, can be carried out. An attempt is being made to establish such a clinic in London. At present this class of work is only being done privately by a comparatively few medical men. This is a field of medicine which needs developing.

Keeping Properties of Syrupus B.P.

Q.—I find that syrupus B.P. is liable to ferment when kept in store for only two or three weeks in a room where there is an electric radiator. Some makes are more susceptible than others. If the syrupus were kept in a cool cellar, would it not ferment? What is the optimum temperature for storing it?

A.—Fermentation is frequently seen in syrup in dispensaries, although syrupus B.P. fully up to the official standard does not itself readily ferment. Any one of a number of factors may contribute to fermentation, and some of the more important points which have to be watched are: (1) The sugar used in making the syrup must be of B.P. quality. Ordinary grades of sugar frequently contain impurities which encourage fermentation. (2) The temperature should be kept as low as possible during manufacture. High temperatures frequently used in large-scale manufacturing produce appreciable quantities of the more readily fermentable invert sugar. (3) The syrup when made should be put into dry bottles when almost cold. It has been shown that dilution with as little as 2% water renders B.P. syrup liable to fermentation, and dilution to this extent may be effected by putting syrup into wet or badly drained bottles. If the bottles are filled while the syrup is still hot, condensation of water vapour may take place and the upper layer of the syrup become likewise diluted. (4) The syrup should be stored in a fairly cool place. Temperature alone will not cause fermentation, but a warm atmosphere will naturally encourage it in a syrup already rendered liable to ferment. On the other hand, storage at too low a temperature is to be avoided, as syrupus B.P. is a saturated solution of sucrose at ordinary temperature, and lower temperatures tend to produce crystallization of this sugar.

Types of Umbilical Hernia

Q.—Is there any record of the value of strapping, with or without a coin, in the case of umbilical hernia in infants? It would be of value to know the relatively immediate results, and also the results on the approach of middle age, pregnancy, etc.

A.—The confusion in the teaching about umbilical hernia in infants is due to failing to distinguish between the two main types. 1. *True Umbilical Hernia*.—In this the protrusion comes through the middle of the remains of the umbilical cord, and carries up with it a kind of fibrous collar from the linea alba. When the sac is empty this collar can be felt under the skin, and the margins of the hole in the linea alba from which it arises are definite and stiff. Hernias of this kind invariably cure themselves; the fibrous tissue round the neck of the sac has an inherent tendency to contract.

They are not dangerous, as, for some not very obvious reason, strangulation of an umbilical hernia in infancy is practically unknown; but they often upset an infant very much, through the discomfort. The infant cries, and the crying increases the protrusion. The spontaneous healing, which may not occur until well on in childhood, can be accelerated in two ways. The first is by strapping with a plain piece of two- or three-inch-wide zinc oxide sticking plaster, applied in such a way as to close the hernial opening by holding a fold of skin over it. Coins, pads, and the common use of elastic sticking plaster all detract from efficiency; and the most inefficient of all is the rubber belt, which is usually, as one mother said to me, worn as a brassière. However, the tendency to spontaneous cure is so strong that all methods have their successes. The second method of treatment is by a subcutaneous ligature of linen. In the roaring and struggling type of baby this will often succeed in curing the condition right away when strapping fails.

2. *Para-umbilical Hernia.*—Here the protrusion is not up the middle of the umbilicus, but slightly above, or less often below. There is no fibrous collar, and the hole in the linea alba is wide, with weak soft margins. This type of hernia is much less common than the first. It has no tendency to spontaneous cure, and an operation is necessary if a good abdominal wall is desired. Strapping and subcutaneous ligature are both useless in its treatment, but a simple longitudinal overlapping of the two rectus sheaths, performed through a transverse incision, is very satisfactory. There is no hurry about operating, as the soft margins of the hernial opening do not cause discomfort, and it can be postponed to 4 years old with advantage.

It is an interesting point whether either of these two types predisposes to the dangerous umbilical herniae of later years. Information on this point, however, will not be gained till knowledge in our profession is more systematically collected than it is now.

Intermittent Hydrarthrosis

Q.—A girl aged 19 complains of periodical effusions into various joints. These occur at irregular intervals, last about a week, and disappear leaving no joint damage. There is no pain, redness, or constitutional disturbance, and they seem to have occurred at irregular intervals since the age of 5. The heart appears normal. B.S.R. (Winthrope) 18 mm. in 1 hour, with 45 c.c.m. packed red cell volume, the blood being taken just after an effusion had occurred. There is no anaemia. She has also seen from time to time spots which look like little "blood spots" under the skin. It has been suggested that this is Schönlein's purpura. What is the most effective treatment to prevent recurrence of these effusions?

A.—This is a case of the condition known as intermittent hydrarthrosis and is probably an allergic response to focal sepsis. The writer has seen such cases develop true infective arthritis later, and this is a possibility seriously to be borne in mind. The slight increase in the sedimentation rate points to the probable presence of a septic focus and the most likely site is the tonsils, which should be carefully investigated. The purpura may also be anaphylactoid nature. Protein shock is probably the most promising line of

treatment, using T.A.B. vaccine, beginning with an injection of 50 units intravenously, increasing at intervals of five days by 50 units for the second dose and 100 millions for the later doses, up to a maximum of 500 millions. Calcium with vitamin D would probably also be beneficial, administered by intramuscular injection and followed later by cod-liver oil as a means of improving calcium retention and raising the general resistance.

It would be of interest to inquire whether the patient suffered from cyclical vomiting in early childhood, which is the case in many allergic subjects. Oriel has pointed out that persons with an allergic tendency easily deplete their glycogen reserve, and the effect of reinforcement of carbohydrates in the diet when the attacks threaten would be interesting. Lichtwitz, in his recent book on rheumatic fever, regards many rheumatic conditions as allergic in nature and brings forward strong arguments to support his thesis. He calls attention to the fact that menstruation may occasionally give rise to effusion of a temporary character into a joint, and Schlesinger has stated that these intermittent hydrarthroses cease during pregnancy. Platelet counts might throw a light on the outbreaks of purpuric spots.

INCOME TAX

Depreciation of Furniture and Instruments

D. M. wishes to claim a depreciation allowance in respect of wear and tear of surgery and waiting-room furniture and instruments. The inspector objects and offers replacement costs instead of the allowance.

* The allowance is given in respect of "plant and machinery," and that phrase has to be construed in accordance with its generally accepted meaning. We consider it would clearly cover large and expensive items of professional equipment—e.g., x-ray apparatus—but doubt whether "furniture" could be brought within it. So far as instruments are concerned, the Schedule D rule provides for the

deduction of sums expended for the supply, repair, or alteration of any implements used for professional purposes, and as both depreciation allowance and cost of replacement cannot be deducted, the inspector of taxes is right in refusing the former.

"Pay as you Earn"

E. P. joined one of the Services in January, 1940, and since then has suffered tax by deduction from his pay, and at the same time deductions in respect of tax on his salary as assistant M.O.H. earned prior to joining the Service. Has he any remedy, or compensation for loss of the tax holiday when he returns to his civil employment?

* Individuals in the service of the armed Forces of the Crown are not within the "pay-as-you-earn" system as such, though tax is deducted currently. This matter was discussed in Parliament during the Budget debates, and the Chancellor of the Exchequer has promised to deal with the matter by making some cash payment to those affected. No information has been forthcoming yet as to how these payments will be calculated or subject to what conditions they will be made.

LETTERS, NOTES, ETC.

The Dilemma of the "Unclean" Nurse

"GENERAL PRACTITIONER" writes from a country district in England: I am tempted to send a note on a situation which sometimes arises, and which I am sure could be tackled by "authority" in a more understanding way. In this district we are blessed with a district nurse who is particularly intelligent and well trained. She adheres to all the rules, is very clean surgically speaking, and thoroughly knows her job. Every now and then, due to no fault of hers—but to drought, dust, and the natural uncleanness of the human species—something septic occurs; the last, and this makes me write, was a cellulitis of the breast following a cracked nipple on the tenth day after confinement. Now, the nurse, in duty bound, reports this to the "local authority" and is counted unclean while looking after this case. As she may do no midwifery this scattered district has either (1) to borrow a nurse from an equally scattered district adjoining, herself overworked; or (2) to get a relief nurse from headquarters, unused to the district, very expensive to the local association, and, as things are, very hard to accommodate. Now is all this really necessary? Either a nurse is trained or she isn't. If she is, she knows as well as I do how to go from one case to another without carrying a load of germs with her. If she isn't, she should not be practising midwifery at all. Obviously the rules are not idle restrictions, and are made to protect the public from gangs and other ghouls; and obviously there are less clean nurses who might be a source of danger. But could not the opinion of the doctor treating the case be allowed to carry some weight? He knows just how septic the case is; and he knows, none better, if the nurse is careful and surgically clean. In the case I quote there seems to be absolutely no reason for all this fuss. When one remembers that the G.P. can be called from whatever he is doing—no matter how septic—to cope with an emergency confinement, and cannot answer that he is sorry but he is feeling too septic to help, it makes these precautions into rather a farce. Moreover, the nurse herself can do dressings, give enemata, and wash dirty old folk to her heart's content, contacting goodness knows what bacterial infections without becoming "unclean." It will, of course, be quite different when this medical millennium we are promised arrives, but in the meantime when supplies of nurses and doctors are short could not an understanding "authority" allow that even C.M.B. rules can be modified when occasion demands, and that a good nurse need not be unclean even when seeing an infected case?

Bee-stings and Fish

Dr. C. R. STEEL (Hartfield) writes: Recently I was stung by bees two hours after a fish lunch and in a short while began to show signs and symptoms usually associated with anaphylaxis. When these had developed to the stage of disfiguring oedema and uncomfortable generalized urticarial rash, the expected relief was obtained with an injection of adrenaline. The swelling and marks of the rash took twenty-four hours to disappear. Dr. R. Stanley in *Bee-craft* of October, 1942, notes the association, which I have not seen recorded previously, of severe reactions following stings in a period when one is sensitive to fish protein. As I had not previously had reactions to either fish or bee-stings the point arises as to whether the dose received in a period of time, considering the sting is allied to a hypodermic injection, is the determining factor as to whether a reaction is experienced or not.

An Improved Saccharometer: Correction

Dr. J. E. STANLEY LEE writes: I regret that, owing to an error in the final draft, the formula was transposed in my note published on June 24 (p. 847). The formula should read:

$$\frac{25}{\text{c.c.m. diluted urine used}} = \% \text{ sugar in specimen.}$$

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JULY 15 1944

CURRENT PROGRESS IN STERILIZATION OF AIR

BY

STUART MUDD, M.D.

Professor of Bacteriology, School of Medicine, University of Pennsylvania

* The prevention and control of acute disease of the respiratory tract is the most serious problem and at the same time the most urgent challenge that to-day confronts medicine in general and industrial medicine in particular. Although diseases and injuries of occupational origin have long claimed the chief interest and attention of physicians in industry, it is now well established and generally recognized that in their frequency and importance non-occupational diseases far outweigh those conditions which arise from industry. The latter are chiefly responsible for stupendous losses in both time and money to employer and employee alike."

The sentences quoted opened an address by George Morris Pierson at the Third Annual Congress on Industrial Health in Jan. 1941. Does examination of available data on industrial disability due to acute respiratory disease indicate that this challenge is being met in current practice? Quite the contrary. The frequency of sickness and non-industrial injuries causing disability for 8 consecutive calendar days or longer among a very large sample of industrial workers over the years 1933-42 has been analysed by the United States Public Health Service (Gafafer 1943a). Sickness absenteeism among males due to respiratory disease has shown a steadily mounting rate since 1938: the rate for 1942 was higher than in any previous year of the 10-year period. For females the rate has been steady since 1939, but at a high level. Moreover, respiratory sickness in male industrial workers in the first quarter of 1943 (Gafafer, 1943b) was far higher than in the corresponding quarter of 1942; indeed, the respiratory rate for the first quarter of 1943 has never been equalled or exceeded during the 10-year period, the first-quarter rate of 1943 exceeding the 10-year mean rate by 52%.

Whatever are the causes of this high and mounting rate of industrial disability due to respiratory disease, common sense cautions us not to seek the complete explanation in the conditions of work in industrial establishments alone. The packing of industrial and other workers in the ill-ventilated common carriers—trains, street cars and buses—since rubber and petrol shortages have been overruling already taxed transportation facilities certainly provides one superlative opportunity for the spread of endemic and epidemic respiratory disease, crowded and confined places of amusement provide another.

In attempting to form even a rough estimate of the cost of this industrial disability, recourse may be had to smaller samples which have been subjected to more detailed analysis. Figures for a public utility for the period 1938-41, inclusive, have been published (Gafafer, 1943c), these show that days lost from respiratory disease are more than a third of the total days lost from all causes of disability. Dr Gafafer has kindly permitted use of a similar table for 1942. This gives the average number of absences lasting one calendar day or longer in a sample comprising approximately 2,500 male and 550 female employees in a public utility in 1942. The average number of

days lost per person during 1942 owing to respiratory disease was for males 3.1 for females 4.3. It is of course understood that the figures for one company cannot be taken as representative of conditions in American industries as a whole. These rates may be either too high or too low. To gain an idea of the approximate cost, if these rates were accurately representative however we may multiply them by the numbers of non-agricultural workers in the United States; these are approximately 26 million male and 14 million female workers (Gafafer, personal communication). This yields an approximate total (with the reservations mentioned) of over 80 million man-days and over 60 million woman days (or over 140 million person-days) lost to industry in the United States through respiratory disease in 1942. On the basis of 300 working days per year, this waste is approximately equivalent to the time of 470,000 persons working for a year.

The Bureau of Labor Statistics publishes monthly data on straight-time hourly earning for manufacturing industries in the United States as a whole (BLS Chart Series, May, 1943). I have computed an average daily earning by multiplying the straight-time hourly earnings (80.5 cents) by 8, the normal working day in American industry.* On this basis the loss in wages due to respiratory sickness amounts to roughly \$900,000,000 per annum. This does not include the expense for medical care overhead expenses arising out of idle machinery, and interruption in production schedules, etc.

Relation between Respiratory Disease and Infectiousness of Air

Persons sneezing, coughing, or even speaking loudly expel into the air large numbers of minute droplets which may contain in a viable and infective state any pathogenic bacteria or viruses present in their oral secretions. The larger of these, potentially infectious droplets have a flight range of about a metre, they are conspicuous, are easily recoverable on bacteriological plates, and their ability to transmit respiratory infection is obvious. When droplets or sputum have dried on solid surfaces their residues may become the source of infective dust.

The role of droplets was notably stressed by the German hygienist Flugge† (1897a, 1897b), and the doctrines of "droplet infection" and dust-infection, or transmission of respiratory infection by droplets and by infective dust, dominated thinking in regard to respiratory disease for 30 years.

The greater part of the potentially infective material expelled by persons into the air, however, is not contained in droplets visible without special means, but in smaller droplets which

* It is unfortunate that daily rates of pay are not available. Since the figure representing costs of time lost due to respiratory disease is at best only an approximate one, the straight hourly earnings (excluding overtime earnings) are multiplied by 8 to secure a daily wage. It is recognized that this is somewhat arbitrary.

† Actually, however, Flugge himself appreciated the importance of invisible droplets accompanying the coarser visible droplets; these, he recognized, may persist in air for hours and reach distant parts of enclosed spaces.

evaporate almost instantaneously. The basic experimental demonstration was made by Wells (1933) and by Wells and Wells (1942) that much of the enormous germ-load conveyed to the atmosphere by the evaporated residues ("droplet-nuclei") of these finer droplets remains viable for hours or even days in the air of enclosed spaces and is wafted about like smoke to convey pathogenic bacteria or viruses to those who share the confined air. The atomizing of mouth-and-nose secretions into the air has lately been revealed with dramatic vividness by high-speed photography (Jennison, 1942). The enormously important role of pathogens floating in confined air in the dissemination of respiratory disease has now been adequately documented by animal experiments, by observations in controlled human environments, and by epidemiological deductions; the evidence to 1941 has been conveniently assembled in *Aerobiology*, a volume published by the American Association for the Advancement of Science with the aid of the Committee on Aerobiology of the National Research Council.

Any attempt to appraise current progress in the sterilization of air must, however, take account of the historical background. Members of the medical profession who now occupy responsible positions in practice, in teaching, and in administration have been thoroughly trained in the doctrine of "droplet-infection." Recognition of the greater importance of true air-borne infection has come only within the past 10 years, and has deeply impressed only the relatively small number of those who have seriously examined evidence which is either very modern or very old. (Of course, important foundations of the germ theory of disease were laid by the studies of Pasteur, Tyndall, and others on micro-organisms in the air.) Lack of a more insistent demand on the part of the medical profession for practical solution of the problems of air-borne infection might seem incomprehensible if this background were lost sight of. Lacking adequate demand by many prominent members of the medical profession for progress in securing pure air-supplies, air-conditioning, from the standpoint of health at least, has somewhat neglected the main point. The point is that, just as intestinal disease has in considerable measure been controlled by reducing the germ-load of water and milk, for the control of air-borne respiratory disease practical measures for reducing the germ-load of confined air must be instituted.

Continuous Disinfection of Air

Effective continuous disinfection of the air of enclosed spaces has already been shown to be practicable where conditions are favourable and where the problem is approached with adequate determination and technical facilities and skill. The practical means are physical (ultra-violet radiation, dust-suppressive measures) and chemical (germicidal vapours). Doubtless physical and chemical means will each find appropriate place as mutually complementary measures in the fully matured art of providing non-infectious air in our future homes, transport vehicles, and places of work and recreation.

Ultra-violet Radiation

Application of ultra-violet radiation to disinfection of air has been systematically reviewed in the A.A.A.S. volume on aerobiology. The physiological and germicidal effects of ultra-violet radiation and the characteristics and standardization of commercially available ultra-violet sources are surveyed in detail. The successful application of ultra-violet radiation to reduction of wound infections in the operating-room is presented by Dr. Deryl Hart, the pioneer in this field, and by Drs. Kraissl and Wilson of Columbia. Cross-infections in hospital wards and in children's nurseries and schools are reviewed and analysed, and success in the reduction of these cross-infections by appropriate use of ultra-violet irradiation is recorded. More detailed analyses of successful control of childhood contagions in schools have been published by Wells, Wells, and Wilder (1942) and by Wells and Wells (1943).

More recent records of germicidal action against bacteria and viruses by ultra-violet radiation in a children's hospital, with reduction in cross-infection, have been published by Sommer and Stokes (1942), by Henle, Sommer, and Stokes (1942), and by Robertson, Doyle, and Tisdall (1943). The Council on Physical Therapy of the American Medical Association (1942,

1943) has found ultra-violet lamps acceptable as an adjunct in the disinfection of air, and commercially available burners and fixtures of several types have been approved by the Council (C.P.T. Reports, 1942, 1943a, 1943b) for use in the operating-room, hospital nursery, and hospital ward.

The statement of the Council on Physical Therapy on acceptance of ultra-violet lamps for disinfecting purposes contains carefully considered appraisal of the present status of the practical art. Pertinent statements are quoted below:

"At the present juncture the design and installation of ultra-violet lamps in their fixtures for disinfecting purposes is empirical and the adequacy of disinfection by any given installation of lamp must be judged by clinical experience. For example, clinical evidence has been submitted to the Council showing that, in a scarle fever ward (size about 60 by 27 by 11 ft.) containing 16 cubicles four lamp units, each one emitting a radiant flux of 30 microwatts per sq. cm. at 1 metre, were found inadequate; but eight lamp units in the ward, each unit protecting two cubicles, and a ninth unit at the entrance, prevented cross-infection. This is a rather high intensity (requiring 20 minutes' calculated time to produce a minimum perceptible erythema) incident on a person of average height, standing directly under a lamp fixture suspended from a ceiling of average height. A greater number of lamps, each one of lower ultra-violet intensity (say, 20 microwatts per sq. cm. at 1 metre) and lower power input, more evenly distributed throughout the room, should be safer and equally efficient in disinfecting the air. This is a matter of engineering design, beyond the scope of the Council's purview. . .

"Since the ultra-violet emission from the low-vapour-pressure mercury discharge tube is practically homogeneous radiation of wavelength 2,537 Å, such a lamp can be readily calibrated in absolute value and used as a standard. The intensity at 1 metre may be only one-fifth of the Council's unit, or 20 microwatts per sq. cm., for safety to the occupants. This will require a minimum exposure of 250 to 500 seconds for adequate disinfection, which will depend on the rate of circulation and average distance of the air in front of the lamp. Evidence has been submitted to the Council showing that cross-infection in a contagious ward may be prevented by using a sufficient number of lamp units, each unit having an intensity of 30 microwatts per sq. cm. at a distance of 1 metre from the burner. This will require an exposure of 167 to 334 seconds for adequate disinfection, which implies a slow movement of the air in front of the lamp installation. . .

"The use of ultra-violet radiation for disinfecting air in industrial plants, barracks, school-rooms, assembly halls, refrigerators, and so on also appears to be outside the Council's purview. In fact, at this juncture the whole question of the use of ultra-violet radiation for disinfecting purposes is too complex and too little understood for the Council to do more than attempt to keep the medical profession informed regarding particular ultra-violet lamps that are acceptable for use in this method of disinfecting air in hospitals, nurseries, and operating-rooms (relatively free from dust) as practised by present-day empirical methods."

It must be emphasized that the Council's statement of acceptance does not prejudice the applicability and the usefulness of ultra-violet radiation to the problem of disinfecting the air of industrial plants, offices, assembly halls, railroad cars, etc. It emphasizes, however, that the specifications of engineering design and other features determining the adequacy and safety of the practical art must be further developed and applied before evaluation will become possible.

Another paragraph of the Council's statement discusses responsibility for design of installations.

"It is to be noted that a lamp used for disinfecting purposes is a single unit in an installation, and that compliance of the ultra-violet output of a single lamp unit with the Council's requirements does not ensure adequate radiant disinfection or the safety of the occupants of the room in which an installation of such lamps is in actual use. Obviously the manufacturer and the distributor of such lamps must assume some responsibility for the adequacy of the lamp installation for purposes of radiant disinfection of the air, and for the adequacy of the protection from injury of the occupants of the space irradiated. Concerning these questions the Council cannot undertake supervision or assume responsibility for the satisfactory performance of any particular installation."

The Senior Biophysicist of the Division of Industrial Hygiene, National Institute of Health (who also is Associate Referee for the A.P.H.A. on Disinfection of Air by Ultra-violet Irradiation), has critically reviewed applications, precautions, and limitations of the use of ultra-violet irradiation to disinfection of air (Hollaender, 1943). The statement of the Council on Physical Therapy is quoted with approval (Hollaender, 1943): "Obviously the manufacturer and the distributor of such

lamps must assume some responsibility for the adequacy of the lamp installation for purposes of radiant disinfection of the air, and for the adequacy of the protection from injury of the occupants of the space irradiated

Acceptance by the engineering groups in whose province air hygiene may be considered as properly falling of a measure of responsibility for elaborating specifications for proper design and servicing of installations would be an important step towards development of a practical art of air hygiene

The efficacy of ultra-violet irradiation in killing air borne bacteria and viruses under conditions in which the air is relatively free from dust and lint has been confirmed in Great Britain by Andrewes *et al* (1940) and by Edward Lush, and Bourdillon (1943). The difficulty of disinfecting dust-laden air by this means has also been emphasized. Andrewes *et al* suggest the combination of air filtration and ultra-violet irradiation in recirculation systems and for certain special purposes

Germicidal Vapours

The spraying of germicides into the air was of course a part of the technique of antiseptic surgery. Modern interest in germicidal mists was stimulated by the demonstration by Douglas Hill and Smith (1928), Trillat (1938), and Masterman (1938) that certain bactericidal substances—e.g. NaOCl and a number of phenolic compounds—when dispersed in the air as fine mists or aerosols exerted a highly lethal effect on air-borne bacteria. Twort, Baker, Finn and Powell (1940, 1942) found that hexyl resorcinol dissolved in propylene glycol made a highly effective and satisfactory germicidal aerosol

An inclusive and practical discussion of the problems of air-borne infection and means for its amelioration in wartime Britain has been presented by Andrewes *et al* (1940). Concerning germicidal mists and vapours they conclude "*Hexyl-resorcinol* in propylene glycol has proved perhaps the most effective under laboratory conditions, but unfortunately neither the antiseptic nor its solvent is at present readily enough available* in large amounts to warrant its introduction except for special purposes

Considerations of economy and practicability as well as of efficacy have served to focus attention in Britain on the germicidal value of hypochlorites and hypochlorous acid. Actually the use of hypochlorites for purification of air was first tried in England as early as the influenza pandemic in 1918. Masterman (1941) reviews in detail the early history and various controversial aspects of the use of hypochlorites for air purification. He describes an atomizing device (dynamalysor) as already in successful operation. "For many months the dynamalysor has been successfully employed for hypochlorite spraying in hospitals, offices and other inhabited rooms, and air purification by hypochlorites is not a scheme 'with definite possibilities' but a successful *fait accompli*". Masterman concludes that HOCl gas is the active germicide in hypochlorite spraying

Bourdillon, Lidwell, and Lovelock (1942) have reported success with hypochlorite atomized by a hand spray in disinfecting air contaminated by sneezing. They note certain unfavourable conditions: "such as low relative humidity or high content of organic matter in the air, which may hinder the action of hypochlorite sprays"

Edward and Lidwell (1943) report favourable tests on sterilization of air borne influenza virus with hypochlorous acid gas. "A concentration of 1 vol of gas in 2 million vols of air is probably effective in destroying 99% or more of virus particles when the proportion of these in the air is small. Preliminary experiments on mice and cats are recorded which failed to reveal any toxic effects produced by inhaling the gas in relatively high concentrations or for prolonged periods. Acute irritation of mucous membranes only was found. This did not appear to lead to any increased susceptibility of mice to subsequent infection with influenza"

Exploration of the possibilities of continuous disinfection of air by chemical substances has made and is making rapid progress in America through the work of O. H. Robertson and his associates. They determined that certain of the glycols alone, notably propylene glycol (Robertson *et al* 1942) and

triethylene glycol (Robertson *et al* 1943) provided promising means for continuous disinfection of air. They demonstrated that the germicidal action depended, not as earlier supposed upon collision of fluid droplets with air-borne bacteria, but upon condensation of hygroscopic glycol molecules upon air-borne droplets containing bacteria. The use of 1 g of propylene glycol dispersed as vapour in 5 or 10 million ccm of air and 1 g of triethylene glycol vapour in several hundred million ccm of air was found to kill pathogenic respiratory bacteria and the virus of influenza in air in seconds or minutes. Rat and monkey colonies kept constantly in atmospheres saturated with vapours of propylene glycol for periods up to 18 months and triethylene glycol up to a year suffered no ill effects detectable by observation or microscopical examination (Robertson 1943b)

The germicidal activity of glycol vapours is markedly influenced by certain environmental factors the most important of which is atmospheric humidity (Robertson, 1943b). A dry atmosphere is unfavourable. Likewise desiccated bacterial particles are not as susceptible to the vapour action as are moist ones. It has been found that the glycols are most effective at relative humidities between 40 and 60%. Subsequent work by Bigg, Jennings and Fried (1944a) and Bigg and Jennings (1944) places the relative humidity for maximal germicidal action of glycol vapours at from 30 to 50%. The former workers indicate also the types of apparatus that are being developed for disinfection of the air of large enclosed places by glycol vapours

Careful investigation of the possibility of fire hazard resulting from the dispersal of glycol vapours into the atmosphere of enclosed spaces has also been made by Bigg, Jennings and Fried (1944b). These authors conclude "In the vapour phase concentration required for air sterilization, propylene and triethylene glycol offer absolutely no fire or explosive hazard. The addition of water to these substances greatly reduces the possible fire hazard produced by their presence in storage or vaporizing devices

Clinical application of glycol vapours during the winters of 1941-2 and 1942-3 is recorded by Harris and Stokes (1942, 1943), working at the Children's Seashore House in Atlantic City. This convalescent home has a relatively stable population, and the children in the wards are confined to their beds, and thus are subject to a minimum of contact or direct-droplet infection. Experimental and control wards were carefully matched, indeed, in the second study (Harris and Stokes, 1943) control and glycol-vapour wards were alternated for three-week periods throughout the respiratory season. Ill effects were not encountered. The germ load of the air was shown to be greatly reduced by the glycol vapours as judged by direct plate counts. In the preliminary study, 2 respiratory infections occurred in the vapour-containing ward as compared with 16 in the analogous control ward. In the second and larger study, 5 respiratory infections occurred in the vapour-containing wards as compared with 100 in the similar control wards without glycol vapour

In his report as Associate Referee on Disinfection of Air by Germicidal Vapours and Mists Prof. O. H. Robertson (1943a) writes: "Practical application of the use of glycol vapours for the purpose of controlling air borne infection has had to await the construction of suitable apparatus for the dispersion of glycol vapours into large enclosed spaces and the development of an instrument to control automatically the concentration of glycol vapour in the air. Rapid progress is being made in the solution of both these problems

Discussion of dust in industry would be outside the scope of this review. Consideration of the air as a vehicle of infection would be very incomplete, however, without reference to the importance of dust both as a carrier of pathogenic bacteria and viruses and as a shield of air borne pathogens against the means used for disinfection of air, such as ultra-violet radiation and germicidal vapours. British investigators (Van den Ende and Andrewes, 1942) in particular, working under wartime conditions have found dust a very serious obstacle to application of measures for disinfection of air. They have introduced practical methods for reducing dust from floors, textiles, and bedclothes by treatment with light paraffin oils (Andrewes *et al*, 1940; Van den Ende and Andrewes, 1942)

* Both hexyl resorcinol and the glycols are available in the United States

Experiments on the reduction of the infectivity of dust by floor irradiation with ultra-violet have been instituted by Hollaender, du Buy, Ingraham, and Wheeler (1944). As a result of these experiments they suggest that "floor irradiation be combined with ceiling irradiation in practical tests in barracks or hospital wards to determine the effect, if any, of ultra-violet irradiation in lowering morbidity rates or preventing cross-infection." They caution that "if such experiments be attempted it must be borne in mind that certain types of flooring may prove to be capable of reflecting sufficient amounts of ultra-violet to cause harmful effects."

I have just (April, 1944) been informed by Dr. Edward Bigg that practical apparatus (Bigg and Jennings, 1944) has been constructed and utilized for introduction into the air of properly humidified glycol vapours. Boiling glycol-water solutions are maintained automatically at any desired relative concentration. "The vapours emitted from such boiling solutions are of constant composition and are bactericidal. . . . A predetermined rate of delivery and concentration of water and glycol vapour may be accurately produced by varying the heat input and the temperature of the boiling mixture" (Bigg, personal communication).

Summary

Respiratory disease is responsible for more than a third of the total number of person-days lost to American industry by disability. The air of enclosed spaces is at present the principal vehicle for the dissemination of respiratory disease. The rationale of rendering air safe for human occupancy has been laid down in the laboratory and in suitable controlled human environments. The means are ultra-violet irradiation, dust-suppressive measures, and the use of germicidal vapours of hypochlorous acid and of propylene and triethylene glycol. Elaboration of the practical art of providing safe air-supplies is, however, not to be accomplished cheaply or through the efforts of a few people. A specialty or specialties in sanitary engineering will have to develop around air sanitation, as has occurred around water and milk sanitation. Physicians, air-conditioning specialists, heating, ventilating, and illuminating engineers, the manufacturers of necessary equipment, agencies regulating public health practice, and the industries which will benefit by reduction of industrial disability through respiratory disease ultimately will all have to contribute effort and money to solving the manifold aspects of the problem. How much is it worth to reduce an annual industrial waste equivalent to the output for a year of approximately 470,000 persons?

INTRAVENOUS BARBITURATES IN THE TREATMENT OF HYSTERIA

BY

CARL LAMBERT, M.D.

Clinical Assistant, Psychiatric Department, Guy's Hospital;
 E.M.S. Neuropsychiatrist

AND

W. LINFORD REES, M.D., B.Sc., M.R.C.P., D.P.M.

E.M.S. Neuropsychiatrist.

The value of intravenous barbiturates in psychiatric treatment remains controversial, despite increased popularity since the outbreak of war. Bleckwenn (1930) is credited with being the first to use intravenous barbiturates in psychiatry; he employed sodium amytal to produce lucid intervals in katatonic schizophrenics, to relieve insomnia, and, in criminological work, to elicit facts from difficult witnesses. Lindemann and Majamud (1934) gave the classical description of the subjective phenomena of light sodium amytal narcosis. They described its characteristic effect as the induction of a feeling of well-being, security, friendliness, and a desire to discuss personal matters not usually spoken of to strangers. Hexobarbitone (evipan) was introduced by Weese and Scharpf in 1932, and two years later was recommended by Hauptmann (1934) as an aid in the production of deep hypnosis. Horsley (1936) described the technique of narco-analysis, using 2½% solution of nembutal and pentothal. He found that psycho-analysis was made considerably more rapid by this method. The value of hexobarbitone in the treatment of neurosis has been stressed by Campbell (1938) and Stungo (1938, 1941). Hadfield (1942) pointed out the value of pentothal in artificially overcoming "blocks" in analysis. Sargent and Slater (1940) found amytal useful in recovering hysterical loss of memory in acute war neurosis. Mallinson (1940) described the technique used in the Navy, and Wilde (1942) reported the use of narco-analysis with pentothal in the treatment of 50 Service neurotics.

Most of the papers on the subject deal with heterogeneous neurotic groups, and tend to stress the advantages of this method of treatment. This paper is limited to one type of neurosis—viz., hysteria—and the results of treatment are compared statistically with those of other psychotherapeutic methods.

The Material

The total material considered consists of 247 successive cases of hysteria admitted to a unit of an E.M.S. neurosis centre. 126 patients received intravenous barbiturate in the course of their treatment. In 19 cases verbal hypnosis was used; the remaining patients were treated by ordinary psychiatric methods without the aid of either intravenous barbiturate or hypnosis. All patients participated in a comprehensive general scheme of treatment, which included various forms of occupational therapy, such as courses of instruction in book-keeping, type-writing, engineering, carpentry, gardening, etc. Remedial physical training formed an integral part of the scheme. Educational lectures and discussion groups also formed part of the patients' activities. Psychiatric social workers were employed when need for them was indicated.

Indications

The main indications for including intravenous barbiturate narcosis in the scheme of treatment were:

1. Cases in which it was considered that ordinary methods of treatment were unlikely to produce speedy recovery.
2. To elicit further information when the causative factors of the case were not clear.
3. To aid production of relaxation in patients with hysterical spastic motor symptoms or contractures.
4. To aid production of deep hypnosis in difficult cases.
5. Cases in which hysterical symptoms had not shown satisfactory improvement, in a reasonable time, at this or other hospitals, by such methods as ordinary persuasion, explanation, and re-education.

The indication varies with the type of symptom. Thus, cases of hysterical amnesia in which interrogation did not produce a speedy recovery of memory were usually given intravenous barbiturate without delay, as it was found to be by far the easiest and quickest method of recovering memory in such cases.

Choice of Barbiturate

The following barbiturates were tested: Sodium amylal (sodium iso-amyl-ethyl-barbiturate), 10% solution, pentothal (sodium ethyl-(1-methyl-butyl)-thio-barbiturate), 2½% solution; and soluble hexobarbitone (evipan—syn. cyclonal—sodium *n*-methyl-CC-cyclo-hexenyl-methyl-barbiturate), 10% solution. It is essential that these drugs be injected very slowly to ensure an even distribution throughout the body so that the required degree of narcosis may be adequately controlled and maintained. When used by the technique to be described we found that, apart from the duration of action, there was no essential difference between these drugs. Sodium amylal is less rapidly broken down in the body than pentothal or hexobarbitone, and therefore exerts its narcotic action for a relatively longer period.

Technique

After a number of cases had been treated it became increasingly apparent that the preparation of the patient and the general technique played an important part in producing therapeutic success. We tried various degrees of narcosis in pre-anaesthetic and post-anaesthetic phases, and found that the pre-anaesthetic phase of light narcosis was the most suitable for psychotherapy.

The technique can be divided into five phases: (1) preparation of patient; (2) induction of narcosis; (3) phase of analysis; (4) removal of symptoms by suggestion and persuasion; (5) continuance of use of recovered functions to full waking state.

Preparation of Patient.—Soon after the patient's admission to the ward full psychiatric and physical examinations are carried out. Rapport is increased by further interviews if necessary. When it is decided to use intravenous barbiturate he is told that he will receive an injection which will aid his recovery. An explanation of his symptoms is given and the nature and mode of action of the injection are explained in terms suitable to his intelligence and personality. He is told beforehand when he will be receiving the treatment, and an attitude of expectation of cure is encouraged. This is reinforced by contact with patients successfully treated by this method.

Induction of Narcosis.—At the appointed time the patient is made to rest comfortably in bed in the treatment-room. The preparations for the injection are ready and the materials at hand. He is engaged in conversation and the venepuncture is made with as little inconvenience to him as possible. Conversation is continued, and the solution is injected very slowly and evenly—not more than 1 c.cm. per minute. As narcosis proceeds the patient becomes progressively more communicative and usually develops increasing suggestibility and mild euphoria. If his speech becomes slurred and indistinct the injection should be stopped, as it indicates that the narcosis is becoming too deep and the patient may go off to sleep, with resulting loss of rapport. This phase may be determined by letting the patient count backwards from 50 and stopping the injection when he repeats a number or counts in normal progression. After some experience this counting technique may be dispensed with, as better rapport can be obtained by just continuing the conversation and ceasing to inject when yawning or slight slurring of speech indicates drowsiness. The desired stage of narcosis can be maintained by the injection of further small amounts of solution if necessary (0.2 to 0.3 c.cm. is usually enough). The quantity of solution required to produce this degree of narcosis varies from 1 to 4 c.cm., depending on the patient's reaction. It is not possible to determine beforehand how much will be required in a particular case.

Phase of Analysis.—As the drug takes effect the patient usually talks with increasing freedom, and the physician limits himself to occasional prompting or follows up clues already gained from the history. The patient must not be hurried, and the session must be continued until it is no longer profitable to proceed. Abreaction of repressed emotion, when it occurs, should be as complete as possible.

Removal of Symptoms.—When the analytic phase is terminated the symptoms can be dealt with by any method of approach

favoured by the physician. The patient's suggestibility is increased and the symptom usually readily removed by firm suggestion and persuasion.

Use of Recovered Functions.—When functional integration is achieved the patient is made to continue using the recovered functions into the full waking state. He is allowed to mix with the other patients and demonstrate his recovery. The continuation of the active use of the recovered functions into the full waking state is important in order to consolidate the recovery. The patient should also be seen the following day for further firm persuasion and encouragement.

TABLE I—Showing Results of Treatment of Hysteria in 126 Service Patients by Means of Intravenous Barbiturate

Group	No	Removal of Symptoms (%)	Considerable Improvement (%)	Slight or no Improvement (%)
Conversion group

Results of Treatment

Tables I and II show the results obtained in the treatment of 247 successive admissions of Forces patients to a unit of an E.M.S. neurosis centre. Table I shows the results in a group of 126 patients treated with intravenous barbiturate. Ten of these patients had previously been treated by persuasion and re-education without success, and so for purposes of comparison with other psychotherapeutic methods are excluded from Table II. Table II therefore gives the results of treatment of 116 patients treated with intravenous barbiturate; 102 patients treated by ordinary psychiatric methods such as explanation, persuasion, and ordinary suggestion; and 19 cases treated by hypnosis.

We have taken symptomatic recovery and functional integration as the criteria for evaluating the results. The criterion of return to duty as an indication of therapeutic success was found to be unsatisfactory for many reasons—e.g., the appropriate disposal depends on the total assessment of the case, and symptomatic recovery is only one of the many factors to be considered. While some patients have to be discharged from the Service in spite of symptomatic recovery, others could be retained for suitable work in spite of their symptoms. It will be seen from Table II that intravenous barbiturate was included in the treatment of about half the total admissions for the period under consideration. Of cases of hysterical amnesia 73% were treated with intravenous barbiturate, and as the results were relatively satisfactory the weighting of the intravenous barbiturate group with cases of amnesia will tend to give an unduly high proportion of therapeutically successful results. It is therefore desirable to compare the groups without the amnesia cases in addition to the groups as a whole.

Comparison of Treatment Results of Total Groups

From Table II it will be seen that 88.7% of the barbiturate narcosis group showed complete symptomatic recovery or considerable improvement; the corresponding figures for the general psychiatric treatment and hypnosis groups are 81.4 and 78.9% respectively, recording an apparently higher therapeutic success rate for the barbiturate narcosis group. The differences, however, are in the realm of chance. The value of "*t*" for the difference between the barbiturate and general psychiatric treatment groups is 1.52 (*P* is between 0.2 and 0.1, and is considerably above the 0.05 level of significance). Similarly the difference in results between the barbiturate narcosis and hypnosis groups is not statistically significant (*t*=0.99, *P* is between 0.4 and 0.3). Comparing only the proportion of those showing full functional recovery, the difference between the barbiturate and general psychiatric treatment groups is greater, but is not statistically significant (*t*=1.77). Similarly the difference between the results of the barbiturate and hypnosis groups is not statistically significant (*t*=0.36).

Comparison of Groups, excluding Cases of Amnesia

When the amnesia cases are excluded the difference in results becomes even less marked. Comparing the proportion of cases showing complete recovery, the difference between the barbiturate and general psychiatric treatment group is not statistically significant (*t*=0.93). The difference from the hypnosis group is also in the realm of chance (*t*=1.1). Comparing the proportion of cases showing complete symptomatic recovery or considerable symptomatic improvement, we find that the differences in results between the barbiturate and general psychiatric treatment and hypnosis groups are again not statistically significant (*t*=1.5 and 0.86 respectively).

The results of treatment of the conversion and dysmnesic groups were compared to ascertain whether the different forms of treatment produced significantly different results.

Conversion Type.—The percentage of cases showing complete recovery and considerable improvement in the three groups are: barbiturate narcosis group, 86.4%; general psychiatric treatment group, 79.7%; hypnosis group, 93%. When these results are statistically evaluated they show no significant differences (*t*=0.95 for difference in barbiturate and general psychiatric treatment groups, and *t*=0.77 for difference between the barbiturate and narcosis groups). Thus there are no statistically significant differences between the results of treating conversion symptoms by the three methods.

Dysmnesic Group.—Taking the dysmnesic symptoms, the proportion of cases showing complete recovery or considerable improvement is 86.2% for the barbiturate group and 85% for the general psychiatric treatment group. The difference is not statistically significant (*t*=0.14).

Motor Symptoms

Intravenous barbiturates were used in the treatment of about half the total number of patients with hysterical motor symptoms. The rapidly acting barbiturates were found preferable for treating motor symptoms, as the patient could be made to continue using the recovered function into the full waking state in a reasonable time. Motor symptoms were usually removed by passive movements, followed by active movements

with the appropriate suggestions. Patients with hysterical gait were made to run as soon as possible. Hysterical contractures were the only hysterical symptoms requiring deep narcosis to ensure adequate relaxation.

The percentage of cases showing complete recovery is lower than that of the group treated by ordinary psychiatric methods. The difference (13.27%) is, however, not statistically significant (*t*=1.18). The difference from the hypnosis group in the proportion of cases showing complete recovery is also in the realm of chance (*t*=0.1).

Stammering.—Recent stammers were fairly easily removed by relaxation and suggestion under ordinary hypnosis. Chronic stammers showed only temporary improvement and usually relapsed after a short interval.

Sensory Symptoms

The main symptoms in the special senses group were varying degrees of deafness and blindness, and usually responded well to suggestion under barbiturate narcosis. In the general sensation group anaesthesias were easily removed by any method. Various somatic pains were found to be by far the most difficult symptoms to treat by any method. The proportion of cases showing complete recovery when treated by hypnosis is significantly greater than that of the intravenous barbiturate narcosis treatment (*t*=2.3). The difference in proportion of cases showing complete symptomatic recovery in the barbiturate narcosis and general psychiatric treatment groups is not statistically significant (*t*=1.01).

In the dysmnesic group we found that intravenous barbiturate narcosis had no advantage over other therapeutic methods in the treatment of somnambulism or hysterical fits.

Amnesia

Intravenous barbiturate narcosis was found to be by far the quickest and easiest method of recovering memory in hysterical amnesia. It was used in all cases in which memory did not recover spontaneously or after a short period of interrogation. Such cases constituted 73% of the total number. The lost memory was recovered completely in 82% of cases; this result is not as high as that obtained for the general psychiatric treatment group (87.5%). The difference, however, is not statistically significant (*t*=0.91). In the intravenous barbiturate group 89.28% showed considerable improvement or complete removal; the corresponding figure for the general psychiatric treatment group is 93.75%. Here again the successes are proportionately higher in the general psychiatric treatment group, though the difference is not statistically significant (*t*=0.59).

In most cases the patient begins talking spontaneously about the amnesic period. If he does not, he is asked to relate the events leading up to that period, and is prompted by any clues previously learned from the history. In a large number of cases facts relative to the main causative factors came out first under narcosis. Though hypermnesia was the rule in the typically hysterical cases, those patients with depressive or anxious preoccupation usually were only able to recall outlines of the period. Most patients recovered memory in one session. Some cases, however, required repeated injections, and often the memory would come back only after the patient had been in hospital some weeks. Most of these cases were found to be those developing amnesia in a depressive setting, and a number had made suicidal preparations or attempts during the amnesic period.

Intravenous barbiturate injections are popularly known as "truth serum" or "truth drugs." Our experience with cases treated by this method tends to show that although, as with alcoholic intoxication, one is more likely to get the truth from persons under barbiturate narcosis, this is by no means invariably so. It is probable that the degree of a person's honesty is not altered. In some cases we found that important information could be deliberately withheld. Two patients gave such fantastic and inherently improbable accounts of their amnesic periods that the stories were considered to be almost certainly untrue. Social inquiry revealed that one of these patients was extremely fond of romancing, and that he was in fact a case of pseudologia phantastica. We have knowledge of a patient who gave detailed accounts of his experiences in

action in France. Later it was proved conclusively that not only had he not been in action but he had not even left the country.

The cases in which memory failed to be restored fell into three groups.

1. *Malingers.*—We found that these cases behaved differently from others. Whereas most patients became communicative under barbiturate narcosis, the malingerer usually became more quiet and guarded. When he was questioned about the amnesic period he would often tend to yawn and go to sleep. Failure to recover memory may suggest malingering in some cases; but of course it cannot be used as proof, as the failure may be due to other causes, such as:

2. *Fugues*, occurring in depressive setting;

3. *Faulty technique*, such as allowing narcosis to become too deep; this probably explains why some physicians succeed after others have failed.

Discussion

Analysis of the results of treating 247 Service cases of hysteria shows that intravenous barbiturate narcosis is no better than ordinary persuasion and re-education. The usefulness of including intravenous barbiturate narcosis in a scheme of treatment varies with the type of hysterical symptom—e.g., it proved to be by far the easiest and quickest method of recovering memory in hysterical amnesia. On the other hand, it was of little value in treating somatic pains. The main advantage appears to be the saving of time; equally good or even better results can be obtained by other methods if one is prepared to devote a longer time to treatment. Thus intravenous barbiturate narcosis is particularly popular in wartime, when usually the time available for the treatment of each patient is strictly limited. The greater rapidity of psychotherapy when intravenous barbiturate is used is probably due to its pharmacological effects of diminishing inhibitions and also, probably, of increasing suggestibility in most cases. The increased suggestibility cannot wholly be attributed to the pharmacological effects of the barbiturate; in fact, Lewis (1941) considers the pharmacological effect to be trifling compared with the suggestive value of the procedure in the achievement of therapeutic success. Our findings confirm this view, and we regard the "psychological preparation" of the patient as of equal importance to the injection, and in some cases as of even greater importance. A number of patients recovered from their symptoms spontaneously during the preparatory phase before the injection had been given. However, each step of the general technique is of value in the achievement of therapeutic success.

Another important aspect of this method of treatment not often realized, but pointed out by Lewis (1941), is the increased confidence of the physician. Compared with verbal hypnosis there is usually less embarrassment to both physician and patient, and as risk of failure is negligible the former's confidence is increased. This increased confidence probably plays a large part in the achievement of successful therapeutic results.

Some specific disadvantages of using intravenous barbiturates were that in some cases great motor restlessness was precipitated, and the patients could only with difficulty be restrained from hurting themselves; also in some cases the physical procedure may tend to confirm the patient's cherished belief that he is suffering from some physical illness. This disadvantage, however, is probably outweighed by the suggestive value of the physical procedure. The results achieved cannot wholly be attributed to the intravenous barbiturate treatment, as essentially it fitted into a general scheme of treatment at the hospital, all aspects of which contributed to the successful outcome. Also it should be realized that barbiturate narcosis is merely an aid to psychotherapy and probably plays only a small part in producing therapeutic success. The success achieved depends mainly on the ability of the physician, his confidence in the method, and the general plan of treatment.

Summary

The results of treatment of 247 Service cases of hysteria are described with particular reference to 126 patients to whom intravenous barbiturates were given.

Various barbiturates were tried, but there was no important difference in the effects produced or in the results obtained.

The pre-anaesthetic phase of light narcosis was found to be most suitable for psychotherapy.

Compared with other psychotherapeutic methods, the main advantage obtained by using intravenous barbiturates was economy of time. This was particularly so with cases of hysterical amnesia, for which it was regarded as the method of choice. Mathematical evaluation of the results shows that, statistically, barbiturate narcosis produces no significantly better results than other psychotherapeutic methods.

The general technique is described, and the importance of the various steps of the technique in ensuring success is stressed.

The suggestive value of the treatment and the increased confidence of the physician are considered to play an important part in the success obtained.

Intravenous barbiturate narcosis may be described as a tactical aid in the general strategy of treatment of patients suffering from neurosis.

We wish to thank Dr. W. S. MacLay for permission to publish the case material.

TWO CASES OF GUNSHOT WOUND RESULTING FROM UNUSUALLY LARGE MISSILES: RECOVERY

BY

RICHARD CHARLES, F.R.C.S.I.

Surgeon, East Suffolk and Ipswich Hospital

I have removed many large missiles from the human body in treating war wounds, but the history of the following cases is of interest because they involved two of the largest foreign bodies that I have ever taken from the chest or abdomen. In both instances the patients recovered.

Case I: Chest Wound

Flight Sergeant B. was hit by "flak" at approximately 18.45 hours on May 7, 1942. He lost consciousness for a few minutes, and on recovering found himself leaning over his gun-hatch. His under-gunner helped him to undo his harness and placed him on the floor of the aircraft. Towards the end of the journey home to his base he apparently became delirious, and his under-gunner had difficulty in restraining him from firing off Vêry lights. About 35 minutes later they landed at an aerodrome.

On admission to S.S.Q., he was greatly shocked, restless, in great pain, cyanosed, and suffering from severe dyspnoea. His blood pressure was 90/50; pulse 140 and very thready. He had a large penetrating sucking wound of the left side of the chest, approximately $3\frac{1}{2}$ by 2 in., situated about 2 in. from the midline at the back, at the level of the sixth and seventh ribs, and running in a forward and lateral direction. A shell fragment which measured $3\frac{1}{2}$ by $5/8$ in. (Fig. 1) was found lying beneath the skin over the eighth rib in

FIG. 1.—Shell fragment ($3\frac{1}{2}$ by $5/8$ in.) removed from Case I.

the mid-clavicular line, at a distance of $12\frac{1}{2}$ in. from the wound of entrance. During its passage into the chest wall the sixth rib was fractured, and the seventh was shattered for several inches, though the overlying skin had not been damaged. Squadron Leader Anderson controlled the parietal haemorrhage, and covered the wound with a large wet dressing and overlapping layers of adhesive strapping. Morphine $1/4$ gr. was given, intravenous serum begun, and 90% oxygen administered by the B.L.B. mask intermittently, and for a short time moderate warmth was applied by a radiant-

heat cradle. A little later the shell fragment was removed under local anaesthesia and occlusive dressing applied.

I saw the patient at the Rest Station at 22.45 hours. His dyspnoea and cyanosis were then less marked; pulse 110 and very steady. There was no apparent intrathoracic bleeding or any sign of tension pneumothorax—the latter not likely to develop in this particular type of wound. He was not, however, in a fit state to be transferred to hospital—a distance of about five miles. During the night two more pints of serum were given, and two further doses of morphine. By 08.00 hours his general condition had slowly but steadily improved, and he was fit to be transferred.

On admission to hospital his blood pressure was 110/70; pulse 116 and of fair volume. Full clinical and x-ray examinations were carried out, and during these procedures he was given a transfusion of one pint of blood; he was then transferred to the operating theatre and received a further pint during the course of the operation, which was carried out under gas and oxygen supplemented by local anaesthesia, using 0.5% novocain (anaesthetist, Dr. Pretty). The skin was washed thoroughly with soap and water, dried, and painted with warm tincture of merthiolate. An elliptical incision was made round the wound of entrance, extending forward to the incision previously made for the removal of the missile; the skin was undermined and widely retracted, and the entire tract of the missile, with all layers, including several inches of the comminuted rib, periosteum, and pleura, was excised *en masse* without permitting the knife or other instruments to touch the tract or the infected surface wound. All used instruments and gloves were then discarded. Blood was evacuated from the pleural cavity by suction apparatus, and a hole in the costal portion of the diaphragm was sutured. Attention was then directed to the lung itself and a careful search was made for bone splinters, pieces of clothing, etc. A portion of the lung was found bruised but not lacerated. The operation was completed by intercostal drainage carried out through a Malecot tube, introduced by trocar and cannula, into the ninth intercostal space posteriorly. The wound was freely dusted with sulphaniilamide powder. The skin only was sutured as far as the wound of entrance, which was packed with vaselined gauze. By this time the patient's condition was very grave; he was pulseless and cyanosed. A pint of serum was quickly given, and on his return to the ward he had another pint, followed by the usual 5% glucose and saline. Oxygen 90% was administered at intervals, and at 18.30 hours his blood pressure was 120/80, pulse 130 and of fair volume, haemoglobin 50%. Two days later sulphapyridine was begun, and subsequently two further transfusions of blood were given. After this his convalescence was practically uneventful.

On May 18 the sutures were removed and the wound had healed by first intention. On May 20 the Malecot tube was withdrawn from the thorax as there had been no sign of intrapleural infection and only a slight serous blood-stained discharge for the first ten days. The wound of entrance was dressed from time to time, and he was finally discharged on June 1.

In Aug., 1943, a letter was received from the patient informing me that he was fit and well, and that he was back on operational duty in the R.A.F., but was not allowed to fly above 5,000 ft. for present.

Case II: Wound of Abdomen

Flying Officer K. was admitted to hospital on June 5, 1943, with a gunshot wound of the abdomen. About 05.00 hours, while returning from an operational flight over the North Sea, he was hit by a large fragment of cannon-shell. He stuffed a handkerchief in the large abdominal wound of entrance and gave himself an injection of one tubonic ampoule of morphine. His pilot crash-landed at 06.10 hours; shortly afterwards Dr. Garnett saw the wounded airman and gave him a dose of alopon. At 07.30 hours he was transferred to hospital under my care, arriving at 10.00 hours.

On examination he was pale, sweating, restless, cold, and shocked; pulse 128 and of poor volume, blood pressure 90/70. A preliminary examination revealed a penetrating wound of the lower abdomen, a laceration of the penis, and a superficial wound of the left leg. Prophylactic doses of anti-gas-gangrene and antitetanic serum were administered, and serum drip was begun. Radiographs of the abdomen showed a large foreign body in the pelvis, and there was a smaller one in the mid-third of the left leg. X-ray examination of the chest was negative. At 11.30 hours one pint of blood was given, and by 13.30 hours he was fit to be taken to the theatre. A second pint of blood, followed by saline and glucose, was administered during the course of the operation, which was carried out under gas-oxygen and ether (anaesthetist, Dr. Pretty). The parietal abdominal wound measured 3 by 2½ in., and there was gross loss of substance; it was situated just lateral to the outer border of the right rectus and its lower end was about 2½ in. above Poupart's ligament. The hole in the peritoneum was about half the size of the missile. The whole abdomen was thoroughly washed with green soap and water, dried, and shaved. The penis wound was then prepared in the same way, and finally the whole area was painted with warm tincture of merthiolate. Laparotomy was performed through the standard midline incision and a fair quantity of blood

in the abdomen was removed by suction. Several small areas of the small bowel were seen to be damaged but not perforated. Two large perforations were found in the pelvic colon running in a longitudinal direction; these were closed in two layers, using fine silk sutures. The damaged areas of the small bowel were then invaginated by pursestring sutures. The foreign body (Fig. 2) was found lying

FIG. 2.—Portion of cannon-shell (1 by 1½ in.) removed from Case II.

loose in the pouch of Douglas. The peritoneal cavity was sprinkled with sulphathiazole powder and the wound temporarily covered with hot abdominal packs.

Next, after a complete change of gloves and gowns, using a closing-tray of clean instruments prepared beforehand, a double-barrelled colostomy was performed in the left iliac fossa, and a Rankin's clamp applied. Sulphathiazole cream was then applied to the abdominal incision, which was completely closed. The penis wound, which consisted of a severe laceration involving the right side of that organ, dividing one half of the corpus cavernosum, was dealt with again, using fresh instruments and gloves. All devitalized infected tissue was removed, including a portion from each end of the corpus cavernosum, and the latter were brought together by an end-to-end suture, using fine silkworm-gut. The wound was left open, and was dressed with sulphathiazole cream and vaselined gauze. Finally, the parietal wound in the abdominal wall was similarly treated. By 17.30 hours his blood pressure was 120/80, and five hours later 130/86.

During the next three days the patient made fairly steady progress. Nothing was given by the mouth during that time; fluids were administered intravenously, but subsequently he began to take sips of glucose, barley-water, and fruit juice.

On June 10 he complained of a pain in the right chest. Temperature 100–103°. X-ray report: "Collapse of the right middle and lower lobes of the lung." A full course of sulphathiazole was begun, and this was continued for seven days. Haemoglobin 69%, W.B.C. 13,000 per c.mm.

June 14.—Respirations 32; pulse 118; swinging temperature 102–102.8°. Still complaining of pain in the right chest, though not so severe. His abdominal condition was satisfactory and the colostomy working well. Radiographs of the chest at this time showed loss of radio-translucency over the whole of the right side, most marked in the middle and lower zones. Haemoglobin, 62%; W.B.C., 28,000 per c.mm.

June 18.—The incisional wound had healed by first intention without the slightest sign of infection. The other wounds had a very mild suppuration, which required occasional dressings.

June 21.—Swinging temperature continued. Night sweats; slight breathlessness but no cough. X-ray report: "Several opacities seen in the right side of the chest. These are greater in the middle and lower zones. ? pleural effusion." In consultation, Dr. Ronald Jones confirmed the previous clinical findings. The following is his report: "There were marked dullness, diminished breath sounds, and impaired fremitus over the whole of the right chest, without any obvious displacement of the mediastinum. The fingers were not clubbed."

July 2.—Chest signs seemed to be diminishing, but fever and sweats still continued and lung abscess was suspected.

July 14.—After a few days' dry cough the patient began to cough up purulent sputum, and 10 oz. was produced. This contained pus cells; the predominant micro-organism was the pneumococcus. No tubercle bacilli were seen. Postural drainage was begun.

July 24.—Some 40 to 60 oz. of pus had been coughed up. General condition much better.

July 29.—Temperature normal, sputum very scanty.

Aug. 3.—Temperature and pulse normal for past five days. No sputum. Chest signs: slight diminution of movement of the right thorax with slight impairment of percussion note and air entry. No clubbing of fingers.

The patient was transferred to a Royal Air Force hospital on Aug. 3; thereafter his convalescence was uneventful. A letter was received from Wing Commander G. H. Morley on Nov. 1, informing me that he had successfully closed the colostomy wound and the patient had made a good recovery.

Comments on Case II

This was a case of pulmonary suppuration probably resulting from atelectasis and infection. Alternatively it may have been metastatic, but if so one would not expect the predominant organism to be the pneumococcus. As there were neither clinical nor radiological signs of cavitation, pulmonary suppuration is a more descriptive diagnosis than lung abscess.

The result of postural treatment was very good, and, owing to this and the absence of cavitation, the question of surgical treatment fortunately did not arise.

By using the midline incision in war wounds the abdomen can be opened quickly, and, what is equally important, it can be closed quickly. It is comparatively bloodless, and can be extended upwards and downwards according to the needs of the case.

In colon injuries, perforated or bruised, exteriorization of the damaged loop as a colostomy is the safest procedure; when this is impossible the wound of the intestine should be sutured and a proximal double-barrelled colostomy of the Devone type performed. In cases of injury to the fixed parts of the colon a separate incision in the flank has many advantages.

The suction apparatus is invaluable in abdominal wounds as, in addition to its many other advantages, it reduces the number of swabs used to an absolute minimum, thereby contributing towards a fool-proof organization in the counting of swabs and packs.

It is interesting to record that the pilot officer, who escaped without a scratch, found 120 cannon-shell bases in the cockpit!

[Figs 1 and 2 are reproduced from drawings by Leonard Squinell.]

A MODIFICATION OF THE INVAGINATION METHOD OF INTESTINAL ANASTOMOSIS

BY

JAMES BURNETT HOGARTH, M.D., F.R.C.S.

Hon. Surgeon, Doncaster Royal Infirmary

In this communication a modified method of performing intestinal anastomosis is described which, it is hoped, will be of use in carrying out this operation quickly and efficiently. The operative technique was devised by me many years ago, and has only recently been employed on the living subject. In view of the measure of success achieved in the cases noted below, which were not ideally suitable for a trial application, I have been encouraged to bring the method to the notice of the profession, before having been able to practise it extensively, in the hope that surgeons in our field hospitals may find it useful.

During the last war Fraser and Dott used the invagination method with satisfactory results in abdominal emergency work in France necessitated through injuries caused by projectiles. They employed the method of temporary occlusion, and although the end-results of their operation and the one to be described are somewhat similar, there are important differences in: (i) the degree of invagination achieved at the site of anastomosis by means of a special instrument devised for this purpose; and (ii) the means of recanalization. Other "aseptic" methods have no doubt been adopted, both in this country and abroad, and any claim to originality on behalf of this method must depend upon the specific use of the two instruments undermentioned—viz., a screw and a pair of sharp-pointed angled forceps. It is hoped that these improvements will lead to the more widespread practice of this type of operation in suitable cases. It effects the union of two temporarily occluded ends of severed bowel and therefore leads to little soiling of the operative field. Preliminary technical investigations were carried out on fresh pig's bowel, and the union obtained was found to be sound and capable of withstanding high water pressure and considerable distension before any sign of leakage occurred round the site of anastomosis.

The special instruments required in addition to those normally available are: (a) an instrument of modified corkscrew pattern (Fig. 3); (b) a modified StClair Thomson angled

forceps; (c) a powerful broad-bladed enterotribe, of the Doyen pattern, and means of heating its blades (the means adopted was a small electric heater).

In describing this operation it is assumed that the part to be removed has been isolated, together with sufficient lengths of healthy bowel on both sides of the lesion to enable the union to be effected. From this point the technique employed is as follows

Technique of Operation

The mesenteric attachments are ligated and divided close to the bowel. This operation is continued on each side of the diseased portion for a distance of one and a half to two inches. Two portions of healthy bowel, adjacent to the diseased part, are now crushed with the enterotribe. Sufficiently wide areas should be crushed to enable the next stage to be carried out. This consists in removing the lesion between ligatures. A "double overhand knot" (Fig. 1) should be used to occlude the healthy bowel-ends,

FIG 1

as these ligatures have to be unloosed by mechanical means at a later stage in the operation. Silk is best for this purpose, as it is much less liable to slip than catgut. For temporary occlusion the pursestring, instead of the stump method, may be adopted so long as the same type of knot is employed. If a heated enterotribe is used for crushing the type of knot is immaterial, as an opening may easily be secured through the "roasted" bowel owing to its friability.

The occluded ends are now approximated, and before invagination are held together by half a dozen interrupted sutures round the circumference of the bowel (Fig. 2). The special "corkscrew" is

FIG. 2

then inserted into the lumen of the bowel with a screwing movement, in the approximate position as shown in Fig. 3, and partly screwed through the double diaphragm formed by the approximated occluded ends (Figs 3 and 4).

FIG. 3

Invagination is produced by holding the distal part of the bowel in the left hand and pushing the diaphragm, by means of the

"corkscrew," into the distal portion (Fig. 4). This can be done easily when there is no great degree of disparity in the calibre of the two segments to be anastomosed, and to the extent of invaginating the mesenteric attachments. Invagination should be effected up to the mesenteric attachments at least. It should be noted that a greater degree of invagination is produced towards the antimesenteric

FIG. 4

than towards the mesenteric side of the bowel because the mesentery interferes somewhat with this process. In this way a good blood supply is ensured towards the antimesenteric aspect of the bowel and thus the risk of subsequent necrosis of that border is practically eliminated. A row of Lembert sutures, continuous or interrupted, is now inserted round the site of invagination, a mattress suture being used where the two mesenteric borders approximate.

The "corkscrew" can now be withdrawn and the St. Clair Thomson angled forceps inserted through the same opening, forcibly pushed through the double diaphragm (Fig. 5), and used in

FIG. 5

a scissors-like manner to obtain recanalization. As soon as this is accomplished the forceps are withdrawn with their blades closed, and the opening left after their removal is closed with a pursestring or other form of Lembert suture (Fig. 6). The operation is now

FIG. 6

essentially complete, and the abdomen is closed, with or without drainage as circumstances dictate. It will be appreciated that a considerable collar of invaginated bowel has been deprived of its blood supply, and this will slough off in the course of healing.

[NOTE.—In the case of the small intestine, where generally the upper segment of bowel is more distended than the lower and is much more friable, it will be easier, safer, and simpler to reverse the process of invagination so that the lower is pushed into the upper portion and, continuity having been restored, to invert the invaginated collar by massage—e.g., in cases of acute obstruction.]

Observations

Reference has been made to the fact that invagination methods have already been used in abdominal surgery. Maunsell's method was devised because it imitated the natural process of adhesive inflammation following sloughing. Although

used successfully on many occasions, it cannot be classed as an operation approaching the principles of aseptic technique. Simple end-to-end suture, and the various mechanical means of procuring circular enterorrhaphy, have the immediate disadvantage of not producing enough invagination of the bowel edges, with the subsequent risk of bowel necrosis towards the antimesenteric aspect. Ullman modified the operation, using a bobbin similar to that of Allingham.

The most successful mechanical means hitherto used for this purpose is Murphy's button. During the last war, as before mentioned, Fraser and Dott elaborated a method of securing end-to-end continuity of bowel by the device of temporary occlusion, without securing much invagination, no form of internal splint being used. The method above described may therefore claim to follow the principles of the Fraser and Dott operation and to achieve the greater degree of invagination secured by Maunsell.

Conclusions

This operation is submitted in the belief that it is: (a) comparatively aseptic if properly performed; (b) rapid and efficient in suitable cases; (c) a method providing free anastomosis with little risk of leakage or necrosis; (d) isoperistaltic in action and has, in the cases in which it has been adopted, resulted in natural bowel action and only slight post-operative distension and pain; (e) a suitable method of union in cases of excision of the caecum or part of the large bowel.

Although opportunity has not hitherto occurred of adopting this method in cases of injury to the small intestine or to gunshot wounds where the degree of injury necessitates excision, it would appear to be particularly suitable.

The following are condensed notes on three cases, all of which are concerned with operations upon the large bowel.

Notes on Three Cases

Case 1.—A woman aged 49. Referred by Dr. Milligan, suffering from carcinoma of the caecum. Very thin and anaemic. Large palpable mass in right iliac fossa. Operation Jan. 14, 1942. A hemicolectomy was performed, and junction of ileum to transverse colon effected by above method. For five days post-operative progress was good and the bowels opened naturally on the third day. On the second day there were signs of inflammation at the site of saline injection. She died from septicaemia on Jan. 24. The post-mortem report stated that the abdominal cavity was clean and the junction was good and patent, with no sign of leakage. There were septic infarcts in the lungs, and abscesses were present in the abdominal wound and behind the posterior peritoneal suture line. The site of the primary septic focus was undetermined, but it was gratifying to find the abdomen clean.

Case 2.—A woman aged 36. Referred by Dr. Shields. Acute intestinal obstruction due to carcinoma of transverse colon. A transverse colostomy was performed by the R.S.O. (Mr. Adlington). This successfully relieved the obstruction. Later (May 7, 1941), as the patient was unhappy about her colostomy, I performed the operation described, through a vertical incision outside the left rectus. Having excised the growth, temporary occlusion and approximation of the two ends of bowel were effected through this opening. Invagination and recanalization were carried out through the old colostomy opening. As a safety measure the colostomy was left open and a T-shaped drainage tube temporarily inserted to ensure the patency of the anastomosis and relieve flatulence. After the return of normal bowel movement the tube was removed and the opening closed by operation. She was discharged completely healed and with normal bowel movements.

Case 3.—A man aged 43. Referred by Dr. Milligan with tentative diagnosis of Crohn's disease. Operation Sept. 9, 1942. Resection of caecum and ascending colon performed. Anastomosis was effected as above. Growth proved to be an adenocarcinoma of caecum. Subsequent progress was very satisfactory. Natural bowel movements returned and flatus was freely passed on the fourth day without aperients. Radiological report by Dr. Miller on barium meal administered on Oct. 2: "Barium passed rapidly through intestinal tract. After four hours no barium in small bowel. After 24 hours all meal was evacuated." The patient was discharged on Oct. 28 with normal bowel action, and is now (May, 1944) quite fit and well. He has carried on his work on the railway for the past year.

My thanks are due to Miss F. M. Lambert, A.R.C.A., for the excellence of the drawings illustrating the operation, and to my son, Mr. T. B. Hogarth, for assistance in the preparation of this article.

METHOD OF LOCATING A MOBILE RENAL CALCULUS AT OPERATION

BY

B. W. GOLDSTONE, B.Sc., M.B.Lond., F.R.C.S.Ed.

Major, R.A.M.C.

The case described below presents several interesting features which will be apparent; but its outstanding feature is that the stone had considerable freedom of movement within the bounds of the kidney. According to its location different syndromes were produced so as to cause, at first, some difficulty in the diagnosis. Because of its changing position, it might have been difficult to locate at operation; a special technique was therefore devised.

When a small stone is known to be somewhere "in the substance of the kidney" (i.e., somewhere in the calical system) several methods have been available for its extraction. In the past the kidney has been split from pole to pole in the hunt for vagrant stones. The method has been used very often; death from post-operative haemorrhage is not uncommon as a sequel. Twelve years ago two patients lay in adjacent beds after a kidney-splitting operation. One died of post-operative haemorrhage. The other announced that he would have a haemorrhage and die; his statement proved correct. The frequency of this complication is not surprising when one considers the immense blood supply of the kidney. One-third of the heart's output goes into the renal arteries (Pickering, 1943). By another estimate, all the blood in the body—about 10 pints—passes through the kidney vessels in three or four minutes (Wright, 1941).

As an alternative to large-scale kidney-splitting, the kidney may be carefully palpated in an endeavour to feel the stone before cutting. This is rarely successful, and then only with a large stone. If this fails it is recommended to "needle" the kidney. The needle can sometimes be felt to grate upon the stone. Even if one is lucky enough to impinge on the stone it may, if free in the calix, be pushed quietly along without yielding any grating sensation. The kidney may also be radiographed on the operating table after delivery through the wound. A cassette is wrapped in a sterile towel and the kidney laid upon it for a picture to be taken. The method needs a long flexible renal pedicle, which is often not available. In that event the cassette cannot be placed close up to or flat against the kidney, and the shadow of that viscus is therefore grossly distorted in the photograph: kidney and stone appear in the picture, but it is impossible to say exactly where the stone lies in relation to the calical system.

The method under description involves none of these disadvantages. It entails insertion of several straight needles into the kidney, which is then radiographed. The needle nearest to the calculus guides the incision. The method is obviously "inspired" by the modern technique for nailing the fractured neck of the femur (Farquharson, 1939).

Case Record

A sailor, already diagnosed as a case of appendicitis, was admitted to a tropical military hospital. At a previous port he had been in a civilian hospital, where appendicitis had also been diagnosed; no operation had been undertaken, as the condition resolved quickly.

Examination showed a heavily built man of 38. He looked quite well and comfortable, and he was apyrexial. He said that he had been subject to attacks of colicky pain in the upper abdomen for several years. The pain was always worse in the right hypochondrium, where it usually began; it then radiated horizontally to the back. He suffered from indigestion, but there had never been jaundice. During the attacks of pain he had no frequency of micturition. There were no physical signs except the Murphy-Moynihan sign (inhibition of expiration on deep pressure over the gall-bladder). Gall-stones were provisionally diagnosed; cholecystography was ordered. This showed a normal gall-bladder shadow. But behind it was a shadow that could have been due to a calculus in the renal pelvis. Intravenous pyelography showed that this shadow was within the shadow of the renal pelvis: hydronephrosis was present as judged by the clubbed calices. The urine contained no pus cells. Under cystoscopy with intravenous injection of methylene blue the dye appeared from the left ureter in 3½ minutes. There was no efflux from the right ureter. Evidently the stone was completely blocking the right uretero-pelvic junction.

The next day he had a brisk rigor. Temperature rose to 103° and he looked very ill. The urine was still free from bacteria and pus cells. Malaria is rife here, and although the parasite was not found in his blood, a white count showed 14% monocytes. This was consistent with malaria, and he was accordingly given a full course of mepacrine. In a few days the fever subsided. Right retrograde pyelography was then undertaken. This showed that the stone was no longer wedged into the uretero-pelvic junction; it was lying in the lowest calix. Urine draining from the right ureteric catheter was loaded with pus and *B. coli*.

It was now evident that the febrile attack had been due not to malaria but to infection of the hydronephrosis; no pus had then appeared in the urine because the pelvis had been blocked by the stone. A course of sulphathiazole was given to control infection of the right kidney. His blood urea was then 85 mg. per 100 c.cm. This was surprising; I would have expected the sound kidney to control his blood urea. B.P. 120/80. After a further course of sulphathiazole his blood urea had sunk to 45 mg. per 100 c.cm., though *B. coli* was still present on urine culture.

This was judged to be the optimum time for operation. Preliminary radiographs showed that the stone was still in the lowest calix. Under general anaesthesia the kidney was exposed by Mayo's incision. Only its lowest pole was visible, projecting beyond the last rib. This rib was therefore removed. Even then the kidney was delivered with difficulty. The pedicle was short and could not be properly seen.

With such a mobile stone it was quite probable that shift could have occurred during delivery. Three round-bodied straight needles were pushed into Brod's line, blunt end first. They covered an area which probably contained the stone, and were pushed in so that they converged radially upon the centre of the pelvis. An x-ray cassette was enclosed in a sterile towel, but it was impossible to obtain proper apposition of cassette and kidney. The picture taken was expected to show much distortion on the kidney shadow; it was rapidly developed. The expected distortion was revealed; but it was immaterial, because the stone was clearly seen to be close to the highest needle. It is unnecessary to set a line of needles at right angles to the first line; the stone must be somewhere on a line radiating from the chosen spot on Brod's line to the centre of the kidney pelvis.

A very small incision was made along Brod's line immediately above this needle. The incision was deepened at once in the direction of the pelvis. This exposed the stone, which was seized and removed. It had the spiked appearance of an oxalate calculus. The kidney was sutured with fine gut on an eyeless needle over a free muscle graft. Recovery was rapid and uneventful except for post-operative pyrexia and some inevitable small-scale haematuria; both cleared up rapidly.

Discussion

It is well known that a renal stone may produce different syndromes according to its locality. In this case there was an opportunity to observe four clear-cut syndromes produced by a single mobile stone. Thus it could give at different times a good imitation of four different diseases according to the stage in which the case was seen by different surgeons.

1. Symptom-free but with pyuria (at this stage the patient might easily have fallen a victim to the pernicious diagnosis of "pyelitis"). The stone was snugly lodged in the calix.

2. The stone emerged, to impact suddenly in the uretero-pelvic junction. This caused upper abdominal pain, principally right-sided. Owing to complete blockage of the right renal outflow there were no urinary changes. Thus the renal origin of the pain was missed and the patient was believed by a surgeon to be suffering from the "first-stage" pain of appendicular colic.

3. Impaction persisted, but the pelvic musculature tired of its peristaltic efforts. The pelvis dilated into a hydronephrosis. This caused a dull pain in the back. The sequence of right epigastric colicky pain which finally radiated to the back, accompanied by a story of chronic indigestion, suggested the diagnosis of gall-stones. The Murphy-Moynihan sign was easily, though wrongly, elicited and this helped to round off the diagnostic picture.

4. The hydronephrosis became infected. The temperature rose rapidly and the clinical appearance was strongly suggestive of pyrexia. Again the ever-present false scent was provided by a mononuclear count. Antimalarial treatment for a few days the temperature was normal. But when the stone was dislodged the stone, all nephrosis to drain.

There remains for discussion the question of the capacity of the kidney alone is quite capable of keeping within normal limits. It follows that this stone somehow have been affected by the right kidney. This is a remark difficult to understand in terms of a

secretion. It is true that several cases have been reported in which unilateral infected nephrolithiasis has caused a general rise of blood pressure. It probably acts by effecting a chemical constriction of all arterioles, including efferent glomerular arterioles but excluding afferent arterioles (Pickering, 1943). Thus the glomerular pressure in the sound kidney should rise and, if anything, more urea should be excreted, because urea is probably secreted by a process of mechanical glomerular filtration and not by tubular secretion. In this patient another unknown mechanism must have been involved, because there was no general rise of blood pressure and there was lessened urea excretion as judged by his raised blood urea.

Summary

A mobile renal calculus, according to its different positions, so changed the clinical picture that the following conditions were successively diagnosed: appendicitis, gall-stones, renal calculus, malaria.

During the phase of infected early hydronephrosis the opposite healthy kidney was affected; no explanation has been found for this.

A method is described for accurately locating the stone at operation. Thus only a small incision in the renal substance was needed; this minimized the risk of gross post-operative haemorrhage.

Medical Memoranda

Fulminating Diphtheria in a War Nursery

A case of fulminating diphtheria in a young child these days must be unusual; when that child has been immunized it becomes something of a rarity. It is therefore hoped that a study of the following cases will prove of interest, and that a few suggestions will help those practitioners who have charge of war nurseries to prevent a similar occurrence.

CASE I

P. L., a boy aged 4, was seen at midnight on March 5, 1944. He had been perfectly well in the morning, but was put to bed after lunch because there seemed to be difficulty in swallowing. He resented being put to bed. Examination of the throat showed nothing abnormal except enlarged tonsils, which were reddened, and a slight increase in temperature. When seen the child was not unduly toxic. Temperature 103°; pulse 170; tongue furred; tonsils grossly enlarged, red, with small whitish patches; some nasal discharge. The cervical glands were enlarged and gave the "bull-neck" appearance. On auscultation heart sounds were quite strong; no abnormal sounds in the chest. A rigor occurred after examination. A clinical diagnosis of diphtheria was made and a throat swab taken. Anti-diphtheritic serum (4,000 units) was given, and sulphanilamide in adequate doses to combat haemolytic streptococci. Early the following morning (March 6) the child's temperature was 101°, the pulse 180, and he was toxic. There was obvious membrane on both tonsils, although the breathing was not obstructed. On auscultation heart sounds appeared weaker than on the previous occasion. A further 2,000 units of A.D. serum were given and arrangements made to send the child to an isolation hospital.

On admission 60,000 units of A.D. serum were given and tracheotomy was performed as a last resource; but the patient died.

Throat Swab.—(1) Morphological diphtheria bacilli present. (2) *C. diphtheriae* present. (3) *C. diphtheriae* present, gravis type. No bacteriological evidence of Vincent's angina or haemolytic streptococci.

CASE II

A. L., twin sister of Case I, complained of a sore throat at 10 a.m. on March 6. She seemed very well; temperature 99°; pulse 130; tonsils reddened only; tongue not furred. At 2.30 p.m. the same day a greyish-yellow patch had appeared upon both tonsils, although the general condition of the patient seemed good. A.D. serum was given, and the child is recovering after being removed with her brother to an isolation hospital. Throat swab—third report: *C. diphtheriae*, gravis type, present.

INVESTIGATIONS AND PROPHYLAXIS

There were 39 children and about 10 staff at the nursery. The problem was to find the carrier and check further outbreaks. The procedure in this nursery is to immunize each batch of children as they arrive, at the conclusion of their medical examination. A.P.T. is used; dosage 0.3 c.cm. first on 0.5 c.cm. second injection. Practically all the children had been immunized except a batch of about six to eight

who were waiting for their second injection. Some of the staff had not availed themselves of immunization. One child (J. W.) had been known to have had diphtheria previously, and was admitted to the nursery in Sept., 1943.

Nasal and throat swabs both of children and of staff were taken on March 7, 1944, with the following results:

		Nasal Swabs		Throat Swabs	
		1st Report	2nd Report	1st Report	2nd Report
Children	..	All neg.	J. W. pos.; rest neg.	All neg.	All neg.
Staff	..	"	All neg.	"	"

J. W. therefore was the carrier. He was immediately isolated. The third report showed *C. diphtheriae* present, gravis type; nasal swab. This child was immediately removed to an isolation hospital. Two of the staff and one child were given prophylactic doses of 2,000 units of A.D. serum. There have been no further cases.

SUMMARY AND COMMENT

A case of fulminating diphtheria occurred at a war nursery; the first patient, who had been immunized, succumbed. His twin sister also contracted the disease, but is recovering; she also had been immunized.

Opportunity was given to observe the development and rapid extension of the membrane.

The carrier was found by means of a nasal swab only. The child had had diphtheria, but had recovered and was admitted to an unsuspecting nursery. It had been in daily contact with 39 children for about six months, but no outbreak occurred until March, 1944.

Investigations showed that the child who died was immunized in Devon in 1941: Aug. 12, 0.5 c.cm. A.P.T.; Sept. 10, 0.1 c.cm. A.P.T.; Oct. 10, third dose, but no stated amount. *Doubt, however, is thrown upon whether A.P.T. was the material used*

It is suggested: (1) Before proceeding to a war nursery (or to school or similar places) children should be immunized. (2) Those who have been immunized two or three years previously should be re-immunized before entry. (3) Where this is not possible, children should be immunized on their first day of entry. (4) Records should be kept of the name and age of the child, the material used, dosage, where immunization was carried out, and, if possible, the name of maker of material used. (5) Children should have throat and nasal swabs taken for K.L.B.; this will show carriers. (6) Any child known to have had diphtheria should be isolated until the results of the throat and nasal swabs are known. This is not foolproof, as a swab which was negative may after a cold be positive. (7) Where there is doubt that the condition may be either a diphtheritic throat or a haemolytic streptococcal throat, isolate immediately and give A.D. serum without waiting for the result of the swab.

My thanks are due to the medical superintendent of Lincoln Isolation Hospital and, for the bacteriological data, to the C.M.S. Pathological Laboratory, Lincoln.

GORDON STRONG, M.B., B.S. Lond.

Adenocarcinoma of the Small Intestine in Father and Daughter

Carcinoma of the small intestine is comparatively rare, accounting for about 3% of all intestinal cancers (Ewing, 1940). At the Mayo Clinic only 76 cases of small-gut carcinoma had been recorded up to 1936. Furthermore, intussusception after the first or second year of life is also rare, and Choyce (1932) states that not more than 12% of all cases of intussusception occur in patients over 10 years. Accordingly the following two cases of intussusception of the small gut caused by adenocarcinoma and occurring in father and daughter appear to warrant publication.

CASE REPORTS

Case 1.—A coppersmith aged 43 was admitted to Llandough Hospital, Cardiff, on June 4, 1940. He gave a history of attacks of abdominal pain for 12 years, relieved by vomiting and the passage of flatus, and on a few occasions had passed some blood in the motions following the attacks. A barium meal showed a normal stomach and the barium enema a distended colon. The occult blood was positive. While in hospital he continued to have attacks of abdominal pain, and when seen in a severe attack on June 23 he presented the features of a small-gut obstruction. Laparotomy, performed by Mr. W. D. Lovelock-Jones, revealed a jejuno-jejunal intussusception, which was easily reduced. Examination then showed that the apex of the intussusception had been occupied by a tumour, and accordingly about 6 in. of gut containing the tumour was excised and continuity re-established by end-to-end anastomosis. Convalescence was uneventful, and he has remained well since.

Pathological Report.—"The tumour has a structure superficially resembling an adenomatous polyp but in many areas showing disorderliness suggestive of adenocarcinomatous transformation. The epithelial cells in many parts are distinctly hyperchromatic and have an anaplastic appearance. In some areas the demarcation between epithelial cells and the supporting connective-tissue framework is disorderly, and there is in parts a heavy infiltration of inflammatory cells. On the whole the appearance is suggestive of a low degree of malignancy."

Case 2.—A girl aged 16, a shop-assistant and daughter of the above, was admitted to Llandough Hospital on Feb. 3, 1943, with a history of abdominal pain and vomiting for about 24 hours, the bowel action being normal. On examination the temperature was 100° and the pulse rate 126 a minute. There was marked tenderness around the umbilicus and in the right iliac fossa, but no mass was palpable. Immediate laparotomy was performed (D B E. F.); this revealed an ileo-ileal intussusception. Reduction by the usual technique was attempted, but the intussusciens then split for about 4 in. In view of this, enterectomy was performed and approximately 14 in. of gut was removed and continuity re-established by end-to-end anastomosis. Post-operative progress was satisfactory, and a year later she is symptomless.

Pathological Report.—"The specimen consists of a resected portion of small intestine 14 in. in length. Ten inches of it, measuring from one end, is deeply congested and shows a condition approaching gangrene. The remaining 4 in. is only slightly engorged and thickened. At the juncture of the two parts there is a pedunculated polyp growing from the wall into the lumen. It is about 1 in. in diameter and roughly spherical, but has an uneven nodular surface and is attached by a thick pedicle. Its surface is irregularly blood-stained. In section the polyp does not show the usual clear demarcation between the glandular part which covers the surface and the fibrous part which forms the pedicle, and an appearance is produced as if there was some degree of invasion of the deeper tissues by the glandular elements. Histologically, the appearance is that of an adenocarcinoma. There is a disorderliness in the arrangement of the gland structures which is not seen in the simple adenoma of the intestine. Gland tubules are irregularly scattered through the connective tissues in the deeper layers and even in the pedicle, and the gland cells show a considerable degree of anaplasia."

It was noted that both patients presented a diffuse brownish pigmentation of the lips and face. On investigating the family history it transpired that the father's brother showed similar pigmentation, and he had been a patient in this hospital in 1935 complaining of attacks of abdominal pain, with the passage of blood and mucus per rectum. A diagnosis of mucous colitis had been made. His health is now satisfactory.

COMMENTARY

The feature of interest is the occurrence of adenocarcinoma of the small gut in father and daughter, causing intussusception. As regards the prognosis of small-gut carcinoma, it is interesting to note that of 31 cases treated at the Mayo Clinic (Rankin and Mayo, 1930) the average duration of life after operation was one year. Harries and Harrison (1935) record two cases of primary carcinoma of the small intestine. Both patients died within three months of the operation, the first with progressive debility and anaemia, the second with metastases in the chest. Mayo and Nettrour (1937) state that the prognosis of carcinoma of the small intestine is unsatisfactory, regardless of whether or not the growth can be removed.

I wish to express my thanks to Prof. J. B. Duguid for the pathological reports, and to Mr. D. J. Harries for his encouragement to report these cases.

Congenital Deformity of the Ribs

Although clinical interest is mainly concerned with supernumerary ribs in the cervical region, a recent case of deformity of the lower ribs seems unusual enough to be worthy of record.

CASE REPORT

A young woman aged 26 was said to have swallowed a pin, and during radiological examination of the alimentary tract a curious abnormality of the eleventh and twelfth ribs on the right-side was discovered. The radiograph of this region (see Fig.) shows the first part of the right eleventh rib curving almost vertically downwards to the level of the intervertebral disk between the eleventh and twelfth thoracic vertebrae, thus forming a kind of neck. The main shaft of the bone then turns away to pursue a normal outward and downward course, but at a considerably lower level than the corresponding rib on the left. At the angle between "neck" and shaft the bone is somewhat thickened, particularly below, and the inferior surface presents a straight facet which articulates with a similar facet forming the top of a short stout process arising from the upper border of the twelfth rib adjacent to the head of the bone

All other ribs were normal in shape and number; there were no other bony processes, and, although the patient had a scoliosis, radiographs of the spine from the sixth cervical vertebra to the sacrum showed no hemivertebrae.

COMMENT

Congenital deformities are described by Brailsford (1935) as bifurcation of the anterior extremity, or fusion with an adjacent rib or ribs just beyond the tubercles, the latter deformity being associated with multiple hemivertebrae of the dorsal spine and large gaps in the bony framework of the thorax. Under the heading of developmental abnormalities, Brailsford also refers to the bands of bone attached to the ribs in myostitis ossificans progressiva, and to osteomata seen in cases of multiple exostoses.

Radiograph showing congenital deformity of the eleventh and twelfth ribs on the right side

In the case reported it was at first thought that the buttress of bone arising from the twelfth rib might be an osteoma or an ossification in the soft tissues. However, the original radiographs showed no other bony processes, and when, in view of a possible myostitis ossificans, the thorax was x-rayed again twelve months later no further changes were seen. Moreover, the condition of the eleventh rib is clearly an alteration of shape, presumably developed before ossification took place, and therefore being a true congenital deformity. It does not, however, conform to Brailsford's description, since the ribs are not actually fused and there are no hemivertebrae, and I can offer no suggestion to explain such an unusual development.

Rupture of Atheromatous Abdominal Aorta

The rarity of complete rupture of an atheromatous plaque combined with the clinical picture of an acute abdomen forms a syndrome interesting enough to merit publication.

A man aged 67 was admitted to hospital with acute abdominal pain; the pain was severe and had come on suddenly at 11 o'clock the previous evening, about half an hour after a meal, since when it had persisted. There was no associated nausea, constipation, or other symptom, and it was located mainly in the right side of the abdomen. On admission his temperature was 97° and his pulse 88. The abdomen was tender and rigid, both in the right hypochondrium and in the right loin, which also contained an indefinite swelling. In the absence of any more definite signs, a non-committal diagnosis of an intra-abdominal catastrophe was made.

At operation a small amount of slightly blood-stained fluid was found in the peritoneum: all the abdominal viscera were normal, but an obvious retroperitoneal haemorrhage was found, mainly on the right side spreading downwards. Pulsation was present in both common iliac arteries, and it was decided that the haemorrhage probably arose from the rupture of an aneurysm of the right renal artery; the abdomen was therefore closed. The patient collapsed soon afterwards and died.

Post-mortem examination revealed widespread severe atheroma of the abdominal aorta, which was thin and friable and contained ulcerated and partly calcified patches. Just above the bifurcation of the aorta one of these atheromatous ulcers had ruptured and produced a large mass of retroperitoneal blood-clot, chiefly on the right side. About a pint of fluid blood was found free in the peritoneal cavity.

My thanks are due to Mr. V. Glendinning for permission to publish this case and to Dr D. M. Vaux for performing the post-mortem examination.

Reviews

INFECTIOUS FEVERS

Clinical Practice in Infectious Diseases. For Students, Practitioners, and Medical Officers. By E. H. R. Harries, M.D., F.R.C.P., D.P.H., and M. Mitman, M.D., M.R.C.P., D.P.H., D.M.R.E. Second edition. (Pp. 570. 22s. 6d., plus 8d. postage.) Edinburgh: E. and S. Livingstone. 1944.

The second edition of this book is a great improvement on its predecessor. It is larger than the first edition by more than 100 pages, contains a full list of references, and deals not only with the clinical and administrative aspect of fevers but with their history and their epidemiology, bacteriology, and immunology. It may now be fairly described as a textbook on fevers and even a work of reference. It is, moreover, well up to date. The literature of the past four or five years is dealt with in great detail. The authors make little contribution of original work, but show much skill in the assessment of the work of others. The chapter on chemotherapy is a model of précis writing, mostly of the Medical Research Council's War Memo. No. 10. It would be difficult, however, to find anywhere a more concise and yet satisfying account of present knowledge on this subject.

Cross-infection in hospitals in particularly well done, and a good account is given of the newer work on bacterial contamination of the air by dust and of the measures suggested for its control. The new work on meningococcal infections, on the pathogenesis of poliomyelitis, and on infective and other forms of jaundice is clearly summarized. Lobar pneumonia and anthrax have not yet found a place in the book. A good account is given of epidemic typhus. As in the first edition, one of the best chapters is that on haemolytic streptococcal fevers. In the way of minor criticism might be mentioned the retention of the intradermal test for hypersensitivity to serum, although dermal and general sensitivity are recognized to be different; the low estimate of incidence of post-vaccinal encephalitis (1 per million); and the too casual dismissal of the aerial theory of convection of smallpox.

This book may now have a greater appeal to the senior reader than to the student. The practitioner, the general physician, and the health officer will find in it a very up-to-date and valuable presentation of modern ideas on fevers.

DERMATOLOGY AND SYPHILOLOGY

The 1943 Year Book of Dermatology and Syphilology. Edited by Marion B. Sulzberger, M.D., and Rudolf L. Baer, M.D. (Pp. 584; illustrated. \$3.00 post paid or 19s.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

The American Year Book of Dermatology has now established itself, and its appearance is welcomed by all those who are interested in the manifold aspects and ramifications of this subject. For eleven years it was under the joint editorship of Dr. Fred Wise and Dr. Sulzberger, but Dr. Wise has now retired and is succeeded by Dr. R. L. Baer, and the introduction of the current volume contains an appreciation of Dr. Wise's services and talents by the new senior editor.

The yearbook maintains the characteristics which have always been associated with it of a comprehensive review of the chief advances in dermatology during the previous twelve months, and is well illustrated. Much is done by the editors to the relief of boredom in their readers. Among other things here is a questionnaire on the cover consisting of twenty searching questions which may well be addressed to those who consider themselves dermatologists, for testing the modernity of their knowledge of the subject. For example, "What are the three commonest disabling complications of 'athlete's foot,' and what is an effective therapy for each?" Again, "What seven skin conditions may be caused by exposure to cold?" It need hardly be added that answers to all the questions will be found in the yearbook itself, which becomes, therefore, a sort of dermatological catechism.

The special problems resulting from the present world war receive adequate consideration. It is to be noted that the tannic acid treatment of burns, which was commended in the last volume, is now recognized as being "out" officially, but we fancy that the editors themselves still have a certain hankering after it. The editors have always begun their volume with an essay on some topic of special interest to the general

practitioner, and this year there is a long chapter on skin tests and their application; it is very comprehensive and well worth study. While emphasizing the value of patch tests in the management of allergic dermatoses they do not hesitate to point out the difficulties and limitations of this method. Included in this chapter is a list of the various bodies in relation to which useful information may be obtained by patch testing. The large number of these substances shows how important the subject has become in dermatology.

SAVILL'S MEDICINE

Savill's System of Clinical Medicine. Edited by E. C. Warner, M.D., F.R.C.P. Twelfth edition. (Pp. 1,168; illustrated. 30s.) London: Edward Arnold. 1944.

Dr. T. D. Savill first published his classical *System* about 36 years ago. It is distinguished by approaching the study of medicine from the symptoms and tracing from these effects to the morbid cause. The sequence of the argument is that which should be adopted in the examination of a patient. He died in 1910, and his widow, Dr. Agnes Savill, has brought out the successive revisions until this one, for which Dr. Warner has the chief responsibility, though he acknowledges her helping hand in the background. The difficulties of producing in these days a new edition of a work to which many authors contribute may well be imagined. It is almost impossible to obtain the co-operation of contributors serving abroad, and during a war medicine tends to produce in rapid succession new discoveries and aspects which must be dealt with. The editor has overcome these difficulties to a remarkable degree, and those who have come to value "Savill" in the past will find this edition in no way inferior to its predecessors.

The discussion of psychological disorders has now been taken out of the section on diseases of the nervous system. The classification of diseases of the blood has been revised to bring it more closely into line with the Savill tradition and to incorporate the many advances which haematology has made in recent years. Dr. Geoffrey Evans explains the mechanism of hypertension in terms of current opinion as an increase in peripheral resistance determined by narrowing of the very small arteries and arterioles, and caused in its turn by the secretion of a pressor substance from the kidney as a reaction to reduction of intrarenal pulse pressure. Accordingly the section on nephritis, especially its chronic form, has had to be largely rewritten. The section on diseases of the thyroid has also been massively revised in accordance with modern teaching. New tables and figures have been added, more notably those which indicate the uses of the sulphonamide preparations and illustrate the x-ray findings in pyorrhoea and apical abscess. Entirely new subject-matter includes the carotid sinus, effort syndrome, mass radiography of the chest, the Rh factor, immersion foot, psychopathic personality, occupational therapy, and many other topics which have recently become of first-rate importance. The index is not really full enough for a reference book of this complexity.

Notes on Books

Synopsis of Materia Medica, Toxicology, and Pharmacology, by Dr. F. R. Davison, is published at 32s. 6d. by Henry Kimpton. Several authors have compiled synopses of this kind, but few of them have been works to recommend. This synopsis, now in its third edition, is an exception, for it can be recommended warmly as a useful work of reference for medical men. Like most American books it is well arranged and well printed. Drugs are classified according to their main site of action, whether on the nervous system or on muscle. The chemical composition of each substance is given, usually also its structural formula, its solubility, its pharmacological action, its toxic effects, and its therapeutic uses. The book contains forty illustrations mostly demonstrating the pharmacological action. Each chapter ends with a list of original papers and books which should be sufficient to enable the reader to follow any line as far as he wishes to go. Books of this kind have a period at which they are at their best. For the first two or three editions they improve as the author takes note of his omissions. Later they deteriorate as the basic matter becomes out of date. This book is now in its best period. The author has successfully coped with the difficulty of becoming acquainted with the great advances in many fields. Later he may not be able to do so, unless as few authors do, he writes the book afresh. It is true that most of the literature referred to is American, but it must be admitted that American literature now covers a very wide field.

Preparations and Appliances

A MAINS-OPERATED SINGLE-CELL PHOTOELECTRIC COLORIMETER

Mr. C J O R MORRIS, Ph D writes from the Medical Unit and the Clinical Laboratory, the London Hospital

Colorimetric methods of analysis have always been used extensively in clinical biochemistry, largely owing to their convenience and rapidity. Such methods have, however, been considered less accurate than volumetric methods owing to the subjective error of colour matching. The advent of photoelectric methods of colour measurement has now removed this objection since it is possible to measure colour intensity with an accuracy of $\pm 0.5\%$, compared with about $\pm 2\%$ for the best visual measurements. Even the last figure is rarely achieved in general laboratory practice, and, in addition the photoelectric method completely obviates the subjective factor. It is thus evident that the photoelectric colorimeter is a very valuable tool for the clinical biochemist, as it enables him to put his colorimetric analyses on a standard of accuracy comparable with volumetric methods while retaining the advantage of rapidity for multiple analyses associated with colorimetry.

The design of photoelectric colorimeters has been studied very extensively, and two types of instrument have been evolved. The first of these is the twin photocell type in which two photocells connected in opposition are illuminated simultaneously, and the "unbalance" current caused by interposing the coloured solution to be measured in one light path is compensated by optical or electrical means a galvanometer being used as null point indicator. The amount of compensation necessary is a measure of the light transmission of the solution. Certain examples of this class have the advantage that variations in light intensity of the source are automatically compensated, since they affect both photocells equally. This is however, not necessarily true for all such instruments, since Müller (1939) has pointed out that certain circuits have the doubtful advantage of only giving complete compensation when the solution to be measured has 100% light transmission. Also if the two photocells have unequal spectral responses a false balance point may be found.

The second type of instrument employs only one photocell, the current produced on illumination being measured directly by a sensitive galvanometer. The principle of this instrument assumes that the galvanometer deflection is proportional to the intensity of the light incident on the photocell. Several workers have demonstrated that this is readily achieved if (a) the level of illumination is low, and (b) the galvanometer resistance is low compared with the photocell resistance. The chief advantages of this type are simplicity of design and rapidity of operation. It is notable that what are probably the most accurate measurements of colour intensity ever made—those of Hogness and his co-workers on haem pigments—were made with a single-cell instrument. The chief disadvantage is that illumination of constant intensity is necessary during the measurement. In the past this has involved the use of low voltage lamps and storage batteries. Recent developments in the design of constant voltage transformers have, however, made it possible to use A.C. mains as the source of power with a constancy of illumination superior to that obtained with storage batteries. The chief criticism of this class of instrument is thus no longer valid. The extremely high sensitivity readily available with the single-cell instrument makes it possible to use very selective light filters, and thus to isolate a narrow spectral band, a property very desirable for certain colorimetric estimations.

The design of either class of instrument involves close attention to both optical and electrical principles, and the instrument described below is presented not as anything fundamentally new, but as an example of the application of these principles to the design of a practical instrument. It has been developed from four years' experience of the essentials necessary in a photoelectric colorimeter for routine biochemistry, and can be readily handled by a relatively unskilled operator.

The principle of the instrument is illustrated in the figure. A is a 6-volt 6 watt tungsten filament lamp (automobile side lamp bulb), which can be run either from a large-capacity storage battery or from A.C. mains with a constant voltage transformer. The lamp can be centred accurately by the grub screws shown. The electrical leads are soldered directly to the lamp, as the use of a lampholder is unsatisfactory. B is the optical condenser, which can be adjusted to give a parallel light beam by a radial lever (not shown). C is the first filter holder with provisions for two light filters. This makes it possible to interpose a filter between light source and solution if necessary. A 2 mm thick Chance color infrared filter is mounted permanently in C. D is the cell carriage. This is provided with a 1-cm thick optical stop which travels with it. The provision of a

thick stop immediately adjacent to the optical cell is an important feature of the design, as by this means reflection from the liquid meniscus and from the sides of the cell is obviated. The carriage is mounted on an arm pivoted at E and extended to form a handle at F. The carriage is traversed by means of F. When F is in the middle of its travel the light beam is interrupted and the filters can be changed without risk of excessive illumination of the photocell.

The carriage will accommodate optical cells of 5, 10, or 20 mm solution thickness. G is the second filter holder with provision for two filters. Iford spectrum filters which cover the visible region in nine steps, are used. H is an iris diaphragm operated by a worm drive to give fine adjustment. I is the photocell (2 cm E.E.L. type) mounted in an eccentric housing for adjustment. It is connected directly to the galvanometer. This is a Tinsley enclosed scale type SS 6/45 sensitivity 800 mm per microamp, coil resistance 150 ohms. The ratio of photocell resistance (approximately 20,000 ohms) to galvanometer resistance is adequate to ensure linearity over a wide range of illumination.

If A.C. mains are used as source of current, the lamp is operated through a type MT 183 230-6 v Advance constant voltage transformer. It is advantageous to connect one primary terminal to one secondary terminal to minimize transformer drift. Where the highest degree of stability is required the MT 183 transformer can be fed from a type MT 161 230-230 v Advance constant voltage transformer, the secondary of the MT 161 being connected directly to the primary of the MT 183. In this case the primary and secondary of the MT are not connected. With this combination a change of 8% in mains voltage produces a change of 0.2% in galvanometer deflection.

The instrument has also been used as a photoelectric spectrophotometer by removing the lamp housing and focusing on the exit slit of a monochromator. The latest instrument has provision for attachment to an optical bench for accurate alignment. The monochromator was illuminated by a 12 v 60-watt tungsten filament lamp fed from A.C. mains through a type MT 140 230-230 v Advance constant voltage transformer and an ordinary 230-12 v transformer.

It is hoped in the near future to develop a modified form of the instrument for fluorescence measurements. A simplified form of the instrument is available for routine use. This differs from the description above in having only one filter holder and a permanently focused optical system.

Operation of the instrument is extremely simple. The lamp is switched on some 10 minutes before use to allow constant light intensity to be attained. With F in the central position, the galvanometer zero is set and the correct filter inserted. The control solution is now brought into the light path and the galvanometer deflection is adjusted to full scale (200 mm) by the iris diaphragm H. The carriage is traversed to bring the solution to be measured into the light path. The galvanometer deflection $\times 0.5$ then gives directly the percentage light transmission of the solution. The extinction can then be calculated from the relation

$$E = 2 - \log_{10} T,$$

where E is the extinction and T is the percentage transmission, or may be read from a table. A calibration curve is made for a given estimation by determining the extinctions for solutions of known concentration. The galvanometer scale is read to the nearest half division, which is equivalent to an accuracy of $\pm 0.25\%$ in transmission or 0.6% in extinction in the usual operating range. The linearity of measurements on solutions of salts like KMnO_4 and $\text{K}_2\text{Cr}_2\text{O}_7$, which are known to obey the Beer-Lambert law, is within this error of measurement. One instrument has been in use in this laboratory almost daily for four years, and has shown no change in linearity of response during this time.

The instrument may be obtained from L. H. Miller, 57, Dulverton Road, New Eltham, S.E.9

SATURDAY JULY 15 1944

AIR DISINFECTION

Air-borne infection is perhaps the largest unconquered field in preventive medicine. It is well recognized as being responsible for the spread of all the infectious fevers and almost all infections of the air passages, from the common cold and influenza to diphtheria and tuberculosis, but beyond improvements in general architecture and in ventilating systems no serious attempt has been made to diminish the spread of infection by this route. That the air of inhabited places does actually contain pathogenic bacteria has been repeatedly proved, and it should obviously not be beyond the wit of man to find some means of destroying or removing them. Regular readers of this *Journal* will be aware that only since the war began has any serious attempt been made to attack this problem in this country. The motive, so far as we were concerned, was the danger of widespread epidemics when large numbers of people were crowded in air-raid shelters, and the valuable work done by Andrewes and his colleagues at the National Institute for Medical Research, designed to discover an efficient method of air disinfection, was undertaken mainly with the object of averting this danger. That no such grave epidemic ever occurred, although large-scale measures to prevent it were never actually brought into operation, is a mystery as well as a fact for which we must all be thankful. Similar but more leisurely studies have been in progress in the U.S.A., not so much with any immediate wartime object but with the larger end in view that the atmosphere of inhabited places generally might be brought to a higher standard of bacteriological purity.

We print in our opening pages a review by Prof. Stuart Mudd of the progress which has been made in this direction. Those who are interested in the subject will find his survey of this wide field a valuable source of information, and any who are not familiar with what has been going on may perhaps be astonished at the scope of this work and the far-reaching effects it is calculated to achieve if the lessons learnt in laboratory experiment prove capable of application on a general scale. The magnitude of the problem is evident from the figures given of industrial disability due to infections of the air passages. The number of hours lost from this cause has increased in the U.S.A. since the war began, and is larger by far than those due to any other condition. There are two principal methods by which air may be disinfected. One is the employment of ultra-violet light, and in the practical application of this method workers in the U.S.A. have been the pioneers. It can be applied in several different ways, the light being either employed diffusely by burners reflecting upwards and disinfecting only the upper layers of air in a room, or directed in the form of curtains protecting a cubicle or other unit

from contamination from without. A third special example is the irradiation of the operation site employed by Hart for safeguarding wounds from atmospheric contamination. The diffuse method of ultra-violet irradiation has been shown, in many practical experiments in the U.S.A., to be capable of restricting the spread even of highly infectious diseases in schools and hospitals, and this method evidently has a valuable future.

The other available methods are chemical, and the earlier work on these originated mainly in this country. The work of Andrewes and his colleagues, of Twort and of Masterman, showed that various disinfectants were unexpectedly active in disinfecting air in the sense that the concentration required was smaller by far than that required, for instance, in water. One possible explanation of this was the aerosol theory of Trillat, who postulated that minute particles of fluid in the atmosphere attracted bacteria to themselves and so brought a high concentration of the disinfectant to bear upon them. This hypothesis led to attempts to produce mists or aerosols composed of fluid particles which persisted for as long as possible without evaporation. It was this consideration which led to the use of glycols as solvents for the disinfectants. Masterman, on the other hand, believed that when sodium hypochlorite was sprayed into the atmosphere its effect was exerted not by fluid particles but by hypochlorous acid gas. Whatever the mechanism of the effect, either sodium hypochlorite or a solution of hexyl resorcinol in propylene glycol was certainly capable of disinfecting air when sprayed to produce a concentration which was harmless to people breathing it. The main advance on these studies achieved in the U.S.A. is the demonstration that propylene glycol itself, used by English workers merely as a solvent, is highly bactericidal. This astonishing discovery has entirely altered the outlook for this method of treating air, since the use of glycols for this purpose is simplicity itself, and the vapour produced is entirely imperceptible and, so far as is known, quite harmless to human beings. Here again practical demonstration of the efficacy of the method in checking the spread of air-borne infection has been obtained in studies made in the U.S.A.

There are therefore, undoubtedly, methods by which the atmosphere of inhabited places can be disinfected so that the transmission of infection from person to person can be checked. It is one thing to prove the efficacy of such methods on an experimental scale and quite another to apply them wholesale. Indeed, it is difficult at present to predict how far such procedures will come into practical use. They have an obvious field in hospitals where communicable infection is known to exist, and their employment in such conditions may be regarded as a certainty. This in itself will be a great achievement, and has many special applications which those who have been concerned with ward epidemics and cross-infection of various kinds will readily be able to picture. To turn these discoveries to practical account in crowded buildings, in public vehicles, and in all those places where respiratory diseases may be acquired from one's neighbour is quite another problem. How far it will be possible or advisable to go in this direction will doubtless depend on local conditions, on season, and on the prevalence or otherwise

of epidemic infection. If there is any serious aspect of checking the spread of the common cold or influenza at all completely it may be asked whether the effect of this would be entirely desirable. One distinguished author¹ has recently suggested that occasional attacks of these infections are the price we pay for some degree of immunity to more serious diseases of the air passages and there is any basis for this idea it may perhaps be inadvisable to go beyond a certain point in protecting the community against air-borne infection.

HIATUS HERNIA AND ANAEMIA

Three types of oesophageal hernia have been described: the congenitally short oesophagus, in which part of the stomach is permanently within the thorax; the para-oesophageal hernia, in which the lower end of the oesophagus remains below the diaphragm and a part of the stomach herniates past it into the thorax; and the gastro-oesophageal hernia, in which both oesophagus and stomach herniate through the diaphragm into the thorax. The para-oesophageal hernia is the most frequent, and by popular usage it has come to be known as hiatus hernia. Similar symptoms may occur in all three types of hernia; these symptoms may be of great variety, and they do not occur in all cases. A broadly dilated oesophageal hiatus, with a freely movable and distensible herniating portion of stomach and a normal pattern of gastric rugae, is far less likely to give rise to symptoms than a hernia which is persistent, fixed, and not distensible, and in which the pattern of the gastric rugae is abnormally prominent. The most typical symptom of hiatus hernia is a substernal pain like angina, which is worse after meals, aggravated by the horizontal position, and often accentuated by emotional stress. Heartburn and regurgitation occur, particularly in the supine position, and the patient may have to stand after meals and read or write with the book on top of the piano. Vomiting may occur without much nausea; haematemesis is not infrequent, but dysphagia is unusual. A symptom which Ohler and Rivo² regard as pathognomonic of hiatus hernia is a feeling of fullness, pain, or distress in the epigastrium or under the tip of the xiphoid, coming on with the ingestion of the first few mouthfuls of food. It may be so severe as to necessitate the interruption of the meal. However, on leaving the table and walking about for a short time the patient experiences a sudden disappearance of the complaints, often with a feeling of something dropping or giving way in the region of the lower sternum. He is then able to return and finish the meal in entire comfort. The explanation is doubtless that the food first ingested fills the herniated portion of the stomach, with distortion, compression, and complete or partial obstruction of the oesophagus; when he gets up and moves about the herniated portion of the stomach empties or reduces itself, and the symptoms disappear.

Hiatus hernia commonly occurs in well-nourished individuals past middle age. Large abdominal tumours favour

herniation, and it is more common in females because of the effects of pregnancy, chronic constipation, and post-menopausal obesity. The symptoms closely mimic those of disease of the gall-bladder or the coronary arteries, and the combination of severe substernal pain and haematemesis may suggest cancer of the stomach. The lesion is easily missed if the patient is x-rayed in the erect position only, and it is essential to make the examination during the ingestion of barium in the supine and prone positions as well as the erect. forcible pressure on the abdomen may reveal a hernia which would be otherwise missed. The shadow of the herniated portion of stomach is picturesquely described as having the shape of an inverted molar tooth; the lower end of the oesophagus is situated asymmetrically in relation to this shadow, entering at the right anterior margin of the herniated fundus.³

Recent writers have commented on the comparative frequency of hiatus hernia and on the high incidence of haemorrhage and anaemia. Sahler and Hampton⁴ found that in a series of 220 cases of hiatus hernia 32 had either moderately severe anaemia or a history of bleeding from the gastro-intestinal tract. They attributed the bleeding to constriction at the hernial ring and, as a result, venous congestion, gastritis, and ulceration in the herniated fundus. The gastritis has been confirmed by examination with the gastro-scope. Murphy⁵ found that, of 7 patients with hiatus hernia or short oesophagus, 66% had some degree of anaemia, and in 27% the anaemia was severe. Erosive gastritis and severe anaemia, which are similarly due to lack of living space, have been observed by Reimann⁶ in severe kyphoscoliosis and attributed by him to compression of the stomach and duodenum and the great vessels in the mesentery. The anaemia of hiatus hernia is usually of the hypochromic type, and it responds well to iron. A curious symptom mentioned by Dyke and Dyas⁷ is pain in the hands. Another patient described this dramatically as like a flame in the hands; there are also tingling and loss of strength in the hands and inability to do fine work. The symptoms are worse with changes of temperature, such as going to bed or exposure to cold. There are no visible changes in the hands, and there is no involvement of the nervous system. Similar symptoms occasionally occur in idiopathic hypochromic anaemia, and they are not pathognomonic of hiatus hernia. Treatment of hiatus hernia is by a diet low in roughage, with avoidance of solid food at the start. Five or six small meals are better than three large ones, and the patient should lose weight if obese. The patient ought to avoid lifting or straining and should rest before meals rather than after; it is helpful to raise the head of the bed. Iron should be given for the anaemia. Operation must be considered if the symptoms are severe and do not yield to treatment, if there is obstruction at the hiatus, or if there is recurrent severe bleeding. In conclusion, hiatus hernia should always be considered in the diagnosis of obscure substernal pain or unexplained hypochromic anaemia, as it is much more likely to be found if it is looked for.

NUTRITION AND THE WAR

Dr. V. P. Sydenstricker,¹ the well-known American nutritionist who was in this country last year, concluded that after four years of war the food situation here was on the whole fairly good. But he thought it a pity that the pregnant woman does not get her unborn child's ration book as soon as she is pregnant instead of ten months later. The effects of slight malnutrition in pregnancy are not detectable clinically and therefore attract little notice; it is only rarely that gross deficiency disease develops. Nevertheless improvement of the nutritional status of the pregnant woman can lower maternal morbidity and cause a reduction in abortion, premature delivery, and stillbirth. It appears that the pregnant woman tends not to get enough vitamin C, animal protein, and fats in her diet. The free cod-liver oil and orange juice now available to her may remedy this in part. The nutritional status of young children is fairly good, for they are provided with vitamin C and cod-liver oil. Growing school-children, however, do not get enough first-class protein—youngsters of 6 get only half a pint of milk daily—and probably not enough vitamin C unless they consume large amounts of "greens." The position of the industrial worker appears to be adequate. Sydenstricker discusses the effect of adding vitamin supplements to the diet of workers to increase their stamina or to enable them to endure excessive and prolonged effort. Controlled observations by Keys and Henschel² and by Foltz and his colleagues³ in America showed that, provided a person is on an adequate diet, supplements of vitamins have no effect on resistance to fatigue, endurance, output of work, or muscular power. Frankau,⁴ however, observed that the addition of nicotinamide to the diet increased the efficiency of fit young men in carrying out a fairly severe test involving physical effort and co-ordination. But fatigue in industrial workers would seem best to be combated by giving extra calories (e.g., in the form of sweetened drinks) and salts to replace those lost in sweat. Sydenstricker rightly deprecates indiscriminate dosing with vitamin pills in place of natural foodstuffs. "It is axiomatic," he says, "that vitamin concentrates and synthetic vitamins should not be used when natural foodstuffs are available in adequate amounts." Jenkins and Yudkin⁵ have shown that there is little to be gained by giving vitamin supplements to adequately fed school-children.

Who can predict the post-war food situation? It will doubt vary in different countries and even in different parts of the same country. The duration of the war will be an important factor. Bread is one of the staple foodstuffs in Europe now, and the fact that it is made from very high extraction flour, other cereals, legumes, and potatoes suggests that there is not likely to be a shortage of the vitamin B complex. The lack of milk, butter, cheese, and meat, however, may be expected to cause a deficiency of calcium, vitamins A and D, riboflavin, and first-class protein. All European countries have done what they can to see that children and expectant mothers come first on the list for protective foods and supplements of vitamins A, D, and C; but many thousands must be in a pitiful plight, and no doubt, when the moment of liberation comes UNRRA won't be slow in coming to their aid. The requirement for synthetic vitamins in post-war Europe cannot be foreseen. The most urgent need will be for calories and protein. G. H. Bourne⁶ advocates the preparation of adequate stores of wheat, dried milk,

dehydrated butter, dried meat and fish, whale oil, soya beans, and supplements of vitamins A, D, and C. Deficiency diseases should be treated in the acute stage with special vitamin concentrates. In this connexion Sydenstricker warns against the use of large doses of vitamin B₁, riboflavin, and nicotinic acid in severely depleted patients: it seems certain that large doses of one of these three vitamins may precipitate a major deficiency of one of the others. In most cases dried brewers' yeast and liver extract appear to be preferable to mixtures of the synthetic B vitamins.

TOXIC POLYNEURITIS AFTER SEDORMID

Sedormid (allyl-isopropyl-acetyl carbamide) is a mild sedative and hypnotic, its potency lying between the bromides and the barbiturates. It has been used extensively on the continent of Europe and in general practice in England, though in hospital practice it has never found much favour. It is not very toxic and is rapidly excreted. Cases of thrombocytopenic purpura resulting from its use have frequently been recorded: in England by Loewy,¹ Torrens,² Joeke,³ and Miller and Rosenheim⁴; in America by Hoffmann,⁵ Moody,⁶ and Huber⁷; and in Germany by Dennig⁸ and Lieberherr,⁹ among others. The thrombocytopenic purpura is quite typical of that condition, being characterized by haemorrhages from the mucous membrane, into the skin and other organs, a reduced platelet count, a prolonged bleeding time, and lowered capillary resistance. Moeschlin¹⁰ attempted to investigate the cause of the condition by sternal-puncture studies and by controlling the rise and fall of platelets during experimental tolerance tests with sedormid in ten cases. During these tests there were no changes in the megakaryocytes, and the "myelogram" remained practically unchanged, except for a slight increase in the erythroblasts as a result of haemorrhages. The tolerance tests showed that in sensitive individuals the platelets would disappear from the blood within half an hour. They must therefore be destroyed in the circulating blood. Yet blood from a sensitive patient at the height of the thrombocytopenia, when given as a blood transfusion, had no effect on the platelets of the recipients. Two or three days after the acute thrombocytopenia a progressive increase in platelets became evident, until after five days normal levels were reached; at first the platelets were immature, which may have been due to an inhibition of maturation of the megakaryocytes. Moeschlin suggested that the cause of these phenomena lay in those nerve centres of the brain that regulate the entire platelet apparatus, but there does not appear to be any concrete evidence to support such an ingenious theory.

Wespi¹¹ quotes Fortanier as describing medullary symptoms, including dysphagia, in a woman aged 52 after taking a course of 51 tablets of sedormid; but she also had purpura, so these symptoms may have been brought about by a cerebral haemorrhage. He also quotes the description by Spanish authors of paresis of the arms and legs in a young girl who took 6 tablets of sedormid; the symptoms were thought to be due to a toxic polyneuritis. Wespi then gives an account of a woman of 21 who attempted suicide by taking 36 tablets

(9 grammes) of sedormid. She did not develop purpura, and her platelet count remained normal throughout her illness; but when she recovered consciousness she was found to have paresis of the right sixth nerve, the right brachial plexus, and the left ulnar nerve. These symptoms cleared completely in the course of a few months. Since both sides were involved, it is unlikely that the symptoms arose from pressure during the period of coma; and the normal platelet count excludes the possibility of multiple haemorrhages into the central nervous system. It seems, therefore, that a toxic polyneuritis must be numbered among the symptoms that can arise from overdosage with sedormid, though there is no account of its ever having arisen with normal therapeutic doses.

VENEREAL DISEASE IN SWEDEN

The spread of venereal diseases has again presented a grave social and medical problem in time of war, and the review¹ of the experience of Sweden in this respect recently made by Dr. Rolf Hallgren is therefore of more than special interest and importance. Venereal disease was rife in Sweden in the seventeenth and eighteenth centuries, and strong measures were taken to combat it during the latter period, but without much effect. In 1812 a Royal Decree was promulgated, replacing local rules. Later, promiscuous women were registered and medically examined at frequent intervals; they also had to conform to certain police regulations. In 1903 a private motion to set up an inquiry was carried in the Diet; this inquiry took seven years, and it was not until 1917 that the proposed Bill took shape. The Venereal Disease (Prevention) Act came into force in 1918; minor amendments have been made since, and at the present time improvements are under consideration. The principles of the existing law are that: (1) Everyone is treated alike: there is no discrimination against prostitutes. (2) Notification is compulsory by the doctor making the diagnosis but is anonymous. (3) Examination and treatment are free during the period of infectiousness (apparently this may be as long as three years in the case of syphilis). (4) The police may be called in to enforce the law. (5) It is a criminal offence knowingly to transmit venereal disease. The Act of 1918 in 19 sections lays down the procedure. There are three official forms of venereal disease—syphilis, gonorrhoea, and soft chancre; lymphogranuloma inguinale was added later. The M.O.H. operates the Act, and treatment is compulsory but free, including free hospital treatment and free certificates. Treatment is carried out by specially appointed medical officers, who are paid according to a fixed scale; there are no *ad hoc* venereal disease clinics.

The procedure is somewhat as follows: The doctor making the diagnosis must explain to the patient the nature of his disease (the parents if the patient is under 15) and give him a pamphlet, which lays down what he must do, including the avoidance of marriage; the patient signs a receipt. If the patient defaults the doctor must try to persuade him to resume treatment; if he does not comply the doctor reports him to the M.O.H. The doctor notifies venereal disease by sex, age, and domicile, but not by name; he must also try to obtain particulars of the source of infection, and he notifies this by name and address to the M.O.H. The latter is enjoined to employ great discretion in dealing with the contact: letters should be in plain envelopes and not marked "O.H.M.S." He orders the contact to be examined and to furnish a certificate that this has been done; the contact must then submit to treatment, if necessary in hospital. The M.O.H. orders all defaulters to resume treatment, and the public health

authority may call in the police to enforce this. A Parish Registrar, on information received, may forbid the banns if any patient suffering from venereal disease contemplates marriage. There is an appeal against the decision of the public health authorities, but pending this orders must be obeyed. The King decides on measures to educate and inform the public, and to make known the obligations of those suffering from venereal disease. Officials or doctors neglecting their duties are liable to fines. Under the penal code anyone who knowingly exposes another to infection is subject to a fine, and, if venereal disease is actually transmitted, to hard labour. Unqualified persons treating venereal disease for gain are subject to fine or imprisonment. It will be seen that our Regulation 33B is a mild version of the Swedish law: mild in that neither notification nor treatment is compulsory, unless a person found to be suffering from venereal disease has infected two or more persons.

Gonorrhoea reached its peak in Sweden in 1919 with 20,651 cases, dropped to 10,006 in 1940, but rose to 19,841 in 1943. In 1942, of 13,747 cases 4,551, or nearly one-third, occurred in Stockholm alone; during the present war the proportion of women to men has been much higher than during the last war; this is thought to be due to the greater number of young females who are promiscuous, and to an increased indulgence in alcohol, both of which are paralleled in Great Britain. Acquired syphilis fell from 6,303 cases in 1919 to 273 in 1941, but rose again to 936 in 1943. Soft chancre, curiously enough, has shown a fairly steady decline throughout the whole period 1918 to 1942, till its incidence is now almost negligible. During the five years 1937–41 in Stockholm 23 to 27% of contacts were reported; in the three other large towns, 17 to 28%; and in the rest of the country 29 to 36%: a substantial proportion of these could not be traced. Naturally the proportion was higher in Stockholm than in the rest of the country.

The Royal Medical Board, which criticized the suggestions for legislation resulting in the Act of 1918, has now made recommendations stressing the need for increasing treatment facilities, appointment of social workers to clinics, provision of prophylactic facilities for males, and an intensive educational campaign, including teaching of sex physiology to the young. It is to be remarked how closely these conform to those made by the Medical Advisory Committee in Scotland, and it is of interest to ponder whether Swedish methods would work as well in Great Britain as they do in Sweden, and whether British public opinion is yet ripe for them. If compulsory notification and compulsory treatment can aid in checking the spread of venereal disease then there is everything to be said for introducing these measures. The experience of Sweden in this war shows, however, that such legislation does not prevent the rising incidence of venereal disease when circumstances favour this.

PENICILLIN IN VIRUS DISEASES

It has usually been assumed that penicillin has no effect on filterable viruses. This is to be expected by analogy with the entire lack of effect on them of other chemotherapeutic agents, and by what little we know or assume about the nature of the action of penicillin. Obscure as this question is, it is generally believed that penicillin interferes in some way with the metabolism of the bacterial cell, and since the metabolic activities of viruses are of the simplest nature they are not likely to be susceptible to this form of attack. Such clinical evidence as is so far available includes no instance of any apparent effect in a virus disease in man. It is therefore

surprising to read in a recent paper by F. R. Heilman and W. E. Herrell¹ that penicillin is effective against experimental ornithosis in mice. The strain of virus used was derived from a pigeon, and initial attempts to treat mice infected by the intracerebral route were without effect. This failure was attributed to the incapacity of penicillin to traverse the blood-brain barrier, and a further series of animals were inoculated intraperitoneally. Treatment was begun at once, consisting of repeated subcutaneous injections of penicillin solution. The mortality in 40 untreated controls was 88% and that in 40 treated only 5%. The controls were found to have characteristic lesions in the liver and spleen which were absent in the treated animals, though virus could nevertheless be detected in these organs by inoculating further animals with suspensions of them. This unexpected result seems difficult to explain except as a direct effect of the drug on the virus. There seems to be no question of its having merely controlled a secondary bacterial infection, as was the case when sulphanilamide was alleged to be curative of distemper and trachoma. The authors have not yet carried out experiments with psittacosis virus, which is much more virulent to mice. This is an obvious extension of the work which must clearly be pursued. If there is anything in the idea that penicillin is effective against viruses, there are many other directions in which this study can be extended in the experimental field before any attempt is made to treat virus infections in man. So far as the direct translation of this work into the clinical field is concerned, there have already been a few scattered observations that penicillin is without effect on what are apparently virus pneumonias.

DIFFERENTIATION OF CULEX MOLESTUS

We have several times recently had occasion to refer to *Culex molestus*, a British mosquito of more than usual interest. This is the bloodthirsty mosquito that has been found breeding in underground levels of the London tube railways, etc., and which seems to have a preference for a subterranean life. Again it is the mosquito which has long given to its near relative, the common British mosquito *C. pipiens*, an undeserved bad reputation, since *C. pipiens* rarely if ever bites man, and it is only the existence of *C. molestus*, which does bite man freely and has been mistaken for *C. pipiens*, that gave rise to the belief that *C. pipiens* did so. Apart from this, *C. molestus* has for some time been of special interest to the scientific entomologist because it was supposed to be a biological race of *C. pipiens* which had developed the very curious and quite unique habit among mosquitoes of being able to lay eggs without a previous blood meal, on which account it was usually referred to as the autogenous form of *C. pipiens*. It may not be irrelevant to note that a very similar case of a mosquito being supposed on account of peculiar habits to be a biological race applies to the so-called races of *Anopheles maculipennis*, now generally conceded to be closely related but distinct species and therefore entitled to any distinctive habits such species may possess. As with these nearly related species of anopheles, so with *C. molestus* the difficulty has been to find suitable structural characters on which differentiation, in this case from *C. pipiens*, can be made in practice. It is therefore very gratifying and helpful that the points of distinction between these two species have been placed on an entirely satisfactory and practical basis in a recent publication of the British Mosquito Control Institute, Haying Island, Hants, under the authorship of its director, Mr. John F. Marshall, C.B.E. Here in a form that even

the non-expert can readily follow is given a most complete and up-to-date account of this interesting British mosquito, its life-history and habits, the localities from which and the conditions under which it has been recorded how it may best be captured and identified, and the methods that can be used in its control. Perhaps for those working on British mosquitoes the most welcome feature of the pamphlet is the very clear statement of the points in which this species differs in structural characters from *C. pipiens*, the surprising thing being that the two species could ever have been confused. These points of differentiation apply not only to the adult—notably the abdominal ornamentation, the absence of patches of pale scales at the ends of the femora and tibiae, especially of the hind legs, and the fact that the last segment of the male palpi lies wholly beyond the tip of the proboscis—but to differences in the larva and notably in the egg raft. It is entirely due to Mr. Marshall's careful work on British mosquitoes that this long-unsuspected species has now come to be recognized, and his account of its morphology and biology is a notable addition to mosquito literature. He will send a free copy to any responsible inquirer who writes to "Wayside," 47, London Road, Cheltenham.

CONTROL OF TRAFFIC IN NARCOTICS

Sir Thomas Russell Pasha, whose vigilance in the Near East effected so salutary a change in the contraband trade in Egypt, has again issued warnings against illicit production of hashish (cannabis) in Syria and the Lebanon resulting in illegal traffic in the drug among the prosperous middle and lower classes in Egypt. The Permanent Central Opium Board, which now meets in London under the presidency of Sir Atul Chatterjee, the Indian delegate, continues to receive reports on the production, manufacture, export, import, and stocks of the scheduled dangerous drugs included in the several international conventions. Some of the Governments party to these conventions, however, are in default in making the statistical returns which are obligatory on the contracting parties. Fifty-two of the 66 metropolitan countries complied with their obligations in respect of the year 1942, and 51 of the 99 colonies and dependencies likewise made returns. Among non-belligerent countries the most serious unexplained gap is that of Spain, which is in default as regards all the required annual statistics. This omission is the more regrettable as there is reason to believe that in the last two years imports of opium and crude cocaine to Spain have reached an abnormally high level. The countries of Central and South America continue to improve their records. Peru, however, has since 1935 furnished either no returns or inadequate ones, though the country produces and exports crude cocaine in large quantities. In 1942 such exports amounted to 2,825 kilogrammes, some of which went to the Argentine, which is not yet a party to two of the conventions. The Board issues a warning of the need for "complete control over the manufacture of, trade in, and distribution of narcotic drugs in the countries, whether enemy or enemy-occupied, as they come under the military and civil control of the United Nations. Unless this is done there is grave danger of a recrudescence of the illicit traffic in drugs and of the spread of addiction, such as was encountered after the last war."

We regret to announce the deaths of two distinguished members of the consulting staff of the London Hospital: Sir William Lister, Consulting Surgeon Oculist to the King, who was also for many years surgeon to Moorfields Eye Hospital; and Dr. Wilfred Hadley, who was also consulting physician to the Victoria Park Chest Hospital.

NICOTINAMIDE = SOME INDICATIONS

● Nicotinamide (nicotinic acid amide) has exactly the same vitamin activity as nicotinic acid, but the flushing and tingling of the skin common with the acid do not occur when the amide is employed.

'Pelonin' Amide, brand of nicotinamide, is specific in pellagra, and in sub-pellagroid conditions manifested by such larval symptoms as indigestion,

irritability, burning of the skin, forgetfulness and insomnia. It is also used in glossitis, stomatitis, dermatitis, diarrhoea and mental disorders associated with nutritional defect. In psychotic disturbances of the aged, the debilitated, the arteriosclerotic and the chronic alcoholic, 'Pelonin' Amide often produces a favourable response.

PRODUCT OF THE
GLAXO LABORATORIES

'PELONIN' AMIDE

Brand of NICOTINAMIDE Ampoules and Tablets (50 mg. in each)

The vasodilatory action of nicotinic acid is itself sometimes desired, as in the treatment of certain vasospastic conditions, e.g., suitable cases of chilblains, Raynaud's disease, trigeminal neuralgia and Meniere's disease. For these, 'Pelonin' brand of nicotinic acid remains available.

GLAXO LABORATORIES LTD., GREENFORD, MIDDX. BYRON 3434

Soneryl

BRAND 1

TRADE MARK

BUTOBARBITONE

is firmly established as the most generally useful hypnotic. There are occasions when even butobarbitone proves to be inadequate and when recourse to a morphine preparation is deemed necessary, but in the majority of cases this product can be fully relied upon as the treatment for those many types of insomnia encountered in general practice. It is because of its proved excellence that 'Soneryl' is frequently described as THE CLASSIC HYPNOTIC.

The **WELLCOME** **MEDICAL DIARY**

PLEASE ORDER *NOW* FOR 1945

Paper is in short supply. Only a limited number of copies of the Wellcome Medical Diary will be printed for 1945. Copies can be supplied only to those doctors who have ordered them. Medical men who have not yet ordered their copy should do so **NOW** *without further delay*, if they wish to avoid disappointment or inconvenience later.

BURROUGHS WELLCOME & CO.

(The Wellcome Foundation Ltd.)

LONDON

A pleasant and effective combination of 'Milk of Magnesia' with a specially selected grade of Medicinal Paraffin. Particularly indicated in the treatment of chronic constipation and hyperacidity of the stomach due to disorder of the alimentary tract.

'MIL-PAR' neutralizes excess gastric acidity and checks the development of acid conditions in the food

waste. Mixing freely with the faecal mass it renders it soft and pliable and lubricates the intestinal tract without formation of oily pools and subsequent rectal leakage.

May freely be employed during convalescence from operation or protracted illness, for infants and children, expectant and nursing mothers.

Contains approximately 2.5% medicinal paraffin and 6% magnesium hydroxide.
SUPPLIES ARE LIMITED BUT SUFFICIENT STOCKS ARE AVAILABLE FOR-DISCRIMINATE PRESCRIPTION

The Chas. H. Phillips Chemical Co. Ltd.

179, ACTON VALE, LONDON, W.3.

'Milk of Magnesia' is the Registered Trade Mark of Phillips' preparation of magnesia.

SELF-MEDICATION AND PATENT MEDICINES

BY

J. N. P. DAVIES, M.B., Ch B.

(From the Physiology Department of the University of Bristol)

The assembly of volunteers undergoing the Medical Research Council haemoglobin survey afforded an opportunity of inquiring into their consumption of medicines not taken under medical direction or advice. Apart from a note by Williams and Hill (1930) on the use of patent medicines by tuberculous patients, the medical literature contains no record of investigation into the details of the individual consumption of patent medicines. So the volunteers were handed a list of medicines, devised in conjunction with Dr H. Heller, and were asked to read it right through and to tell the observers what they used and the details of its consumption. Those taking a remedy under medical advice were ignored. The descriptive terms of the questionnaire were varied so as to bring to the mind of the person questioned the wide range of medicaments and their different forms that might be taken. Aspirin was given a place of its own, as it is employed for so many different purposes. The only real difficulty in assigning a medicine to its appropriate category was in the case of milk of magnesia, which seems to be used more for its laxative than for its stomachic properties. It is included under the vague heading of "Bowel Medicine."

The results are set out in Tables I and II. 277 persons were questioned, comprising factory workers (mostly engaged in light engineering) office, laboratory, and laundry workers, nurses, business men, and A R P full time staff. The wording of the questions is shown in the first column of Table I. All above the age of 15 years were put through the test. The questions were always answered cheerfully and courteously and without embarrassment, and at no time was it felt that subjects were concealing their use of the medicines suggested to them. By an oversight the use of "cold preventives"—e.g. calcium—was not inquired into. No questions were asked about substances taken for sexual disabilities, venereal diseases, etc., real or imagined, as it was felt that this would put too great a strain on the subjects' honesty. But from some of the statements made there is good reason to think that there is still a considerable trade in medicines for venereal disease.

Self-medication in Relation to Age and Sex

Table I shows that a slightly larger proportion of females (78%) took medicines than males (72%), but the difference is statistically insignificant. Out of 277 questioned only 11 were taking gastric sedatives (even including those taking milk of magnesia). This is striking as it is generally believed that the consumption of such substances by the general population is very high. Several factory medical officers suggested that about 10% of the male operatives regularly used them. The very low percentage revealed by the survey may be a truer index of the state of affairs, or it may be evidence of selection.

There is the possibility that sufferers from chronic gastric disorders are not of the temperament that volunteers to lose blood even in small amounts. Hence they are missing from surveys such as this—a point of rather wide implication. With the exception of those suffering from skin troubles and a very few in obvious ill health, the majority professed themselves as thoroughly healthy. Thus this is a survey of the medicines taken by healthy people.

The total of 277 persons was rather too small to submit all the results to statistical analysis, as when broken down into small groups there were too many void classes, so it was decided to set out the results directly in the hope that, though too small now, they might be built into a larger series later. However, the relation between self medication and age for each sex is shown in Table II. For all ages combined the proportion

TABLE II—Self medication by Age and Sex

Ages	No of Observations		No not taking any Medicine		No taking One Medicine		No taking More than One Medicine	
	M	F	M	F	M	F	M	F
15-	27	67	6	16	10	39	11	12
25-	41	26	10	5	20	18	11	3
35-	43	18	15	2	20	9	8	7
45+.	38	17	11	5	20	7	7	5

A comparison of the age distribution of those taking medicine and those not taking medicine gave

	χ^2	P
Males	1.76	0.63
Females	2.02	0.57

of males who took more than one medicine was slightly but insignificantly larger than for females, the percentages being 25 and 21. For both males and females the proportion taking medicines was independent of age. This appears most important, as it would be expected that the greatest consumption of medicines would occur during the ages when physiological stresses are at their maximum. For instance, at the menopause it might be expected that the proportion of women taking medicines would be much higher than in the 25-35 age group. This finding clearly suggests that the consumption at all ages is dependent not on physiological or pathological demand but on advertisement and suggestion that if there were no advertisements to induce the public to believe that they need such medicines there would be little demand. While this is true over the whole range of medicines it seems to be true also of each type of medicament, although no attempt has been made to express this statistically. Self medication may in rare cases be a product of serious defects in our social life (*Our Towns* 1943), but it would seem that there is no real need for any patent medicines of any sort, and that the present demand is almost entirely the result of advertisement.

Aspirin

Aspirin is used for many purposes—for headaches, for colds and chills, for any rheumatic pains, even as a sleeping draught. It is a remedy more favoured by women than men. 44.5%

TABLE I—Self medication Related to Occupation

[illegible]

of the females and 21.5% of the males took aspirin—a significant difference between the sexes of 23.0 ± 5.6 . Regular users appeared to take it for headaches and not for rheumatic ailments, as there is not a rising incidence with increase in age; throughout the survey it was noted that the heaviest occupational incidence of aspirin-taking was among those engaged in dry indoor work, laundry workers (in dry posts), and female factory workers, and the incidence was low in A.R.P. workers in outdoor occupations. Nowadays aspirin is almost as much a drug of addiction as is morphine. Habit plays an enormous part in the consumption of aspirin. All three women taking aspirin daily did so to ward off headaches; only one of the five taking it at least weekly used it as an antirheumatic. Headache powders were also chiefly used to ward off and not to relieve headaches. One woman took two tablets of a proprietary compound four-hourly three days a week to ward off headaches. And very successfully, it appears, for she never has headaches; but she is lucky that the Government has protected her against worse things, for the tablets she takes contained amidopyrine until it was placed on the Fourth Schedule. We are ignorant of the remote effects of many common and seemingly harmless substances when used with such intensity over a long period of time. Few of these people had or ever had had headaches, but they took these substances as preventives.

Laxatives

As might be expected, laxative medicines were very extensively used, the salines markedly predominating over the vegetable laxatives. The percentage incidence of takers was highest in the office and laboratory workers and lowest in the A.R.P. workers, who lived a more or less open-air life. The habit factor was strongly shown by the saline-takers, more taking regular doses than those taking doses irregularly. The vegetable laxatives were for the most part taken irregularly, as the spirit or the state of the bowels suggested. Of recent years there appears to have been a swing from the use of the stronger vegetable laxatives to the milder salines, probably correlated with sustained and clever advertising. The influence of advertising is probably again shown in the gross predominance of one particular saline and one particular vegetable laxative. This does not seem to be due to any wartime zoning or rationing, but to be a matter of personal preference.

It is probably in relation to laxatives that the words "harmless and beneficial" (Viscount Gage, 1938) are most commonly applied. Yet besides the general objections to the regular use of laxatives (Hurst, 1924) many specific complaints have been voiced. In particular, liquid paraffin has been indicted. It is known to interfere with vitamin A absorption (Curtis and Ballmer, 1939) and also with vitamin D, calcium, phosphorus, and vitamin K (Council on Food and Nutrition, A.M.A., 1943). It is thus a most undesirable laxative to use when a patient is in need of these substances—e.g., in pregnancy. But I am indebted to Dr. F. J. Lewis for the information that of 12 pregnant women attending an antenatal clinic six were using liquid paraffin, some of them daily for over five months. One imagines that their Ministry of Food vitamin supplements were rather wasted. (The women are not included in this survey.) There is little doubt that laxatives used regularly over a lengthy period will cause deleterious effects. That a daily cascade of salines through the bowels may cause serious decrease of absorption of, for example, iron is possible, and it is known that calcium absorption is affected. Meulengracht (1938) reported a case of osteomalacia of the spine following the daily ingestion of Carlsbad salts (sodium sulphate and sodium bicarbonate) every morning for 35 years. No such striking case can so far be quoted against the vegetable laxatives, but there is no doubt of their harmfulness (Clark, 1938). Mass Observation (1943) report that there has been an increase in the taking of salines and laxatives in wartime, but mention no figures. They also state that there has been no increase in the taking of digestives.

The "Preventive" Group

The results of the inquiry into the taking of the group broadly known as preventives—iron, vitamins, etc.—were most disappointing. This group, it might be thought, would be used extensively after the propaganda of the last few years. Yet

only 18 out of 277 were taking any of these substances supposedly so beneficial, and half of these were laboratory assistants, mainly engaged in biological work, and two more were nurses. (Ten nurses were given iron and vitamins by the hospital authorities.) Thus only 7 out of 240 of the general workers took either iron or vitamins, and many of the females badly needed iron. It has recently been announced that the Ministry of Food is to insist that vitamin preparations must conform to certain specifications. But surely it is equally essential that iron preparations should not be sold as purporting to cure anaemia unless they contain adequate amounts of iron. Mass Observation (1943) report that preventives, including calcium as a cold-preventive, were taken by "many people." They also state that there has been an increase in vitamin-taking in wartime. The incidence suggested would appear to be much higher than that found in this survey. The explanation may lie in the introductory words of their bulletin—that the surveyed were an "unusually thoughtful" section of the population.

Comment

The two most gratifying aspects of the survey were: first, that the more exotic and extravagant remedies were not much used—a fact noted by Clark (1938); and, secondly, that there was a widespread desire for information among those questioned. They desired good health, and many quite sincere thought that they were ensuring it by the taking of the medicines. The majority of those surveyed were ostensibly healthy people, and when the high proportion taking drugs noted we may well wonder at the probable extent of self-medication among the sick folk. The excuse of poverty lacking, as all those surveyed were covered by national health insurance, and it is a curious fact that the public have no faith in medicaments that can be obtained cheaply. While always recognizing the therapeutic powers of faith and hope, even in patent medicines, it is more than time that steps were taken to protect the public—both the sick and the healthy—from exploitation. Mr. A. L. Taylor of the Bristol Royal Infirmary has kindly estimated the cost of many of these substances in relation to their purchase price, and his figures reveal that there has been little improvement on the conditions revealed in *Secret Remedies* (1909). In fact, as Lord Horder said in 1938, in the last 25 years, with the increased extent and power of advertisement, the public is being swindled on a larger scale than ever before. The 1941 Act has checked a few of the more grotesque abuses, but the uselessness of the Act in really improving the sorry state of affairs is shown by a perusal of Chapman's book (1942). In view of the experience of Edwards and Kinsie (1940) it would be wise to be sceptical of the possibility of improving matters by increased education, for they found, after three years of intensive campaigning against venereal disease, that the persons surveyed were more ignorant than ever, and that the number of drug stores where counter-prescribing and the sale of patent nostrums went on was greater than ever. Every advance in medicine is mirrored by an extension of the patent medicine manufacturers into the same field. Recent belated action by the Newspaper Proprietors' Association (1943) in the censoring of advertisements will do little to help. Their ban does not go beyond the "code" of the members of the Proprietary Association of Great Britain (Chapman, 1942). For harmful substances can still be advertised and sold, and impressionable people will still be intimidated into using the advertised medicaments. Very few sick people are able to read dispassionately and discriminately advertisements of substances purporting to cure or relieve the ailments from which they suffer. To prevent much public exploitation and ill-health restrictive legislation is imperative.

Summary

The results of a census of self-medication among 277 persons engaged in various occupations in Bristol is presented.

The present data show that self-medication is independent of age for both males and females. For all medicines combined there was no difference between the sexes. Differences existed for specific remedies: the use of aspirin by females was significantly greater than by males, but the majority of the medicines involved too few persons for definite conclusions to be drawn.

Some specific groups of medicines and their effects are briefly discussed.

I wish to express my thanks to the Medical Research Council and Prof. R. J. Brocklehurst for permitting me to make this survey; Dr. H. Heller, Mr. A. L. Taylor, and Mr. W. R. Lush for their valuable help; and especially to Mr. Horace Todd, who performed statistical analyses.

SAFETY IN OPERATING THEATRES AND ANAESTHETIC ROOMS

MEMORANDUM BY INSTITUTION OF ELECTRICAL ENGINEERS

In February, 1938, papers were read before the Institution of Electrical Engineers by the late Prof. W. M. Thornton and Dr. E. H. Rayner, and as a result the question was raised whether the Institution ought not to take the initiative in arranging for the discussion of safety in the electrical equipment of operating theatres and their ante-rooms, where there would appear to be danger of explosion of anaesthetic vapours. The Council was impressed with the wisdom of this course, and it was agreed that the Institution should set up a suitable committee to consider: (1) The electrical conditions and design of equipment necessary for the elimination of the risk of explosions. (2) The desirability of a Code of Safety Rules. (3) The arrangements which are appropriate for ensuring that safe equipment is installed and safe conditions are maintained.

Under the chairmanship of Mr. H. T. Young, the Operating Theatres Electrical Apparatus Committee was formed and appointed two technical subcommittees to carry out its work, one to deal with questions of static electrification, and the other to deal with apparatus, installation, and maintenance, with Dr. E. H. Rayner of the National Physical Laboratory and Mr. H. W. Swann of the Home Office respectively as chairmen. These committees began their investigations in February and March, 1939, but before much progress had been made the deteriorating political situation and the evacuation of many large hospitals from London caused the suspension of the work. However, in May, 1943, a communication was received from Dr. C. F. Haddfield, on behalf of the Council of the Association of Anaesthetists of Great Britain and Ireland, requesting that the work of the committee should be resumed, and a ready response was forthcoming from the council of the Institution.

It had become clear at an early stage that the elimination of danger from anaesthetic explosions must depend mainly upon the provision of safe electrical conditions and apparatus, and that, to achieve this, arrangements would need to be made to ensure that safe equipment was installed and that safe conditions were maintained. After having considered the advisability of drawing up a brief safety code, the committee unanimously adopted a suggestion put forward by Mr. Swann, that the detailed recommendations of the committee should be expressed in the form of a distinctive Warning Notice of a size and form adequate for display in operating theatres and similar locations where explosion risks might exist, so that its guidance should be constantly before not only the anaesthetists and surgeons but also the nursing and other staff employed.

In November, 1943, the Warning Notice in its final form was submitted to the council of the Institution, when it was decided that it should be sent to the Minister of Health with a request for distribution by the Ministry to hospitals, nursing homes, etc., in England and Wales; it was further agreed that, if it were adopted by the Ministry of Health, it should also be sent to the Scottish Office and to the Government of Northern Ireland for a similar purpose.

In Mar. h, 1944, the committee learned that the Minister of Health had convened a representative interdepartmental conference, attended by representatives of the interested Government Departments, at which the decision had been taken to circulate the Warning Notice to all voluntary hospitals and to all hospital authorities in this country, and, through the agency of the Admiralty, War Office, and Air Ministry, to all Service hospitals in this country and abroad, after certain omissions and modifications had been made. It was also decided to delete the references to published work which had been given in the original Notice, but to include them in a covering letter sent to hospitals, etc., in this country.

At a meeting in March, 1944, the council of the Institution noted the dissemination that had thus been assured for the Notice, and authorized the publication of the Warning Notice in its revised form [reproduced in the *Journal* of July 1, p. 19], together with the present

memorandum, which contains a note of the more detailed recommendations contained in the original draft. It was felt that as changes and re-equipment may be carried out in individual hospitals from time to time, it would be desirable that the medical and electrical experts concerned should be made aware of the full precautions which the Council of the Institution recommend. The major departures may be summarized as follows.

In their review the members of the committee were of the opinion that a very real risk existed that the persons of operating personnel might become charged with electricity, and an appropriate reference in this regard was made in paragraph (c) of the introductory matter. The paragraph also points out that the risk of a spark occurs when an object is brought nearly into contact with another at a different electrical potential. In the list of precautions and recommendations the committee added a recommendation to item 2 that when operations were finished for the session or for the day, all the ether should be removed from the apparatus.

In connexion with the equipment of operating theatres it was recommended that electric lamps connected to the main supply should be fitted with protecting shields of metal, glass, or other suitable material, and in the list in item 7 of the insulated apparatus which can be electrified in various ways portable anaesthetic equipments were included.

The important question of earthing received additional attention, and in connexion with item 8, which points out that trailing chains are useless when the floor is covered with dry, non-conducting rubber, cork carpet, or linoleum, the additional recommendation was made that in such cases carthings may be effected by attaching the chains to water pipes or to some other suitable earth connexion. The last sentence in item 9, suggesting that under war conditions damping of the floor may have to be adopted as an alternative to the use of special "conducting rubber," was added in the course of the revision of the original notice.

In dealing with the state of the atmosphere in the operating theatre, the committee in its original recommendations drew attention to the value of maintaining a satisfactory degree of humidity and put forward the recommendation that equipment for conditioning the air of the theatre should provide adequate and continuous control of humidity (approximately 60 to 70%).

References to Scientific Work

In the circular letter issued by the Ministry of Health to establishments in England and Wales (Circular 53/44 of June 4, 1944) a list of the references to scientific work which has been carried out on this subject was included, and for convenience these are set out below.

Memorandum 191 Med. published by the Ministry of Health (H.M. Stationery Office, price 1d.)

Regulations for the Electrical Equipment of Buildings, 11th edition (revised), issued by the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2, price 1s.

KHARTUM SCHOOL OF MEDICINE

The seventh report, 1939-42, of the Kitchener School of Medicine, Khartum, records continued progress in spite of wartime difficulties. Graduates from the school have served as officers in the Sudan Defence Force—both within and outside the Sudan, and also in the Civil Medical Service. The course of professional studies consists—at present—of a year and a half at the School of Science and four years and a half at the Kitchener School of Medicine. The two teaching hospitals at Khartum and Omdurman provide the opportunity for all Sudanese medical graduates to spend two years in resident appointments in medicine, surgery, obstetrics and gynaecology, and ophthalmology.

A few lines may be quoted from the sympathetic and constructive Visitor's Report, 1942, by Major-General W. H. Ogilvie, consulting surgeon, M.E.F. "The hopes of Gordon, Kitchener, and Stack, men who loved the Sudan and sought its welfare, are here embodied, in a scheme to which those who are responsible for Britain's stewardship in developing countries can point with satisfaction. The present directors of the school are working in the spirit of that stewardship, determined to provide a centre of medical education which, though small, is of high quality. The searching character of the final examination, the insistence that all subjects must be taken at the same time, the 60% pass level, and the practice of inviting visitors from Britain to observe and comment, are evidence of a policy that aims to maintain and even improve a standard that is already high."

MEDICAL SICKNESS AND LIFE ASSURANCE

At the recent annual meeting in London of the Medical Sickness, Annuity and Life Assurance Society, Ltd., Mr. R. J. McNeill Love, chairman of directors, who presided, referred first of all to the special concessions which the Board of Directors had made to Service members. Before the war benefits were virtually restricted to the United Kingdom, but claims, not in respect of enemy action, were now being paid in any part of the world during in-patient treatment in hospital or from the day of embarkation if the member was invalided home. Prisoners of war were exempted from payment of all sickness premiums until they were repatriated. With regard to life assurance, the Board had resolved in principle to exclude only death due directly to enemy action, and it was hoped to pay in full all other claims, whether arising on Service or not. Over £4,000 had already been paid in claims to members who had been ill while over-seas. The chairman also announced that a special subcommittee had been appointed to consider the White Paper on a National Health Service; the Board was interested in its possible repercussions upon private practice. The annual report showed that new business in the Life Assurance Fund in 1943 totalled £185,780 for annual premiums of £5,779. Claims by death were higher at £30,079. The increase to £68,548 paid in benefit under the sickness fund was due to influenza and also to the decision to pay claims from over-seas. The invested funds had been increased by £217,268, and now stood at well over £2,750,000, more than 43% of the total being in British Government securities. The Board had arranged new head offices at 7, Cavendish Square, and when the time arrived the Society would move back to London from its temporary quarters at Highfield, Chesterton, Cirencester.

MEDICAL PROTECTION

The annual meeting of the London and Counties Medical Protection Society was held at Victory House, Leicester Square, on June 7, with Mr. W. M. Mollison, treasurer, in the chair. Sorrow was expressed at the death of Sir Cuthbert Wallace, who had been president of the Society since 1935, and until the beginning of the war was a regular attendant at its council and committees. The office of president remains vacant for the time being. Mr. Mollison said that the past year—the fifty-first in the Society's history—had been one of continued progress. There had been less litigation over trivial matters, but several important cases had been fought and won by the Society on behalf of its members. The number of applications for advice and assistance amounted to nearly 1,000. The net gain in membership had been 576. The income showed an increase, and the accumulated funds had now reached £96,400, with an investment reserve of £7,000 in addition. During the year, owing to the uncertainty as to the obligations of medical practitioners to report deaths to coroners, the Society and the Medical Defence Union had obtained the opinion of Mr. Roland Burrows, K.C., president of the Medico-Legal Society (see *Journal*, Nov. 27, 1943, p. 694). He understood that a number of members had applied for copies of this opinion. The report and statement of accounts was adopted, all the retiring officers and members of council were re-elected, and on the motion of Sir Robert Hutchison a vote of thanks was accorded to the staff and to the solicitors, Messrs. Le Brasseur and Oakley.

Nova et Vetera

HARVEY CUSHING'S LIBRARY

The Harvey Cushing Collection of Books and Manuscripts. Edited by Prof. J. F. Fulton. (Pp. 205. \$8.50.) New York: Schuman's. 1943.

A private library of historical medical books is an expression of the development of a personality. A real collection is formed by slow accretion, and at each stage it reflects the literary interests of its collector. The late Harvey Cushing was early in the field, inspired by Osler, the prince of collectors and stimulators. When Cushing died in 1939 he left a charming essay on a Vesalian collection,¹ now reprinted in his posthumous work on Vesalius, and from this and other sources we surmise that Cushing must have started the unending quest for old medical works in the latter part of the '90's, when he was just under 30. From then to the time of his death he collected with enthusiasm and discrimination. In more recent years the need for specialization became evident, and he had a working arrangement with his friends Arnold Klebs and John F. Fulton.

Klebs was to concentrate more on incunabula and Fulton the seventeenth century. The result is that Cushing's collection is particularly rich in anatomical and surgical texts of the sixteenth century. The whole of the three libraries mentioned have gone to form the kernel of the Historical Medical Library at Yale, and the present catalogue is the first to appear of the three which will describe this nucleus.

It is of interest to compare the Cushing collection with other libraries which have been catalogued in recent years, and especially with that of Osler, Cushing's mentor.² The Cushing collection contains about 7,900 entries; that of Osler has about 7,800. Osler has 54 editions of Hippocrates against 1 of Cushing, but Cushing has 42 of Ambroise Paré against 17 of Osler. They appear to have been almost equally interested in Galen (about 60 editions each). Cushing is peculiarly weak on Celsus; perhaps he considered Celsus merely as disseminator. Osler's own catalogue of his collection was based on the example of Ferguson's *Bibliotheca Chemica*, a catalogue of the Young collection,³ and it is to be expected that the latter would be much richer in books dealing with the development of pure science. Outstanding examples are the editions of Albertus Magnus, Glauber, Hermes Trismegistus and Raymond Lull in this collection. Both Cushing and Osler compare favourably (about 20 editions) with the Paracelsus editions in the Young collection; but all these are driven into the shade by the 201 editions of Paracelsus which Ferguson had in his own library, a catalogue of which (limited to 4 copies) has recently been published⁴ by Dr. W. R. Cunniff, the Hunterian Librarian at Glasgow. It has also been very interesting to compare the Cushing library with the collection of early medical books owned by the late Dr. Le Roy Crummer.⁵ On Albertus and Aristotle Crummer has it but otherwise there is little in his collection which is not represented in Cushing, and the latter's editions are sometimes earlier. Cushing is also especially rich in Culpepper, Guenther, Berengar da Carpi, Mondino, Boerhaave, Cardan, Tagault, Boyle, and Harvey. The manuscripts and incunabula are excellent. There are certain weaknesses which possibly throw some light on the tastes of the collector. Of the *Religio Medici* he has nothing earlier than Keynes's No. 6, and the Wilkins collected edition is not included. He has only the facsimile of the first edition of Auenbrugger's *Inventum Novum*; while the Fernel collection is good, there are unexpected omissions; and while he has the catalogue of Mead's pictures, he does not have the catalogue of his library. There is no original edition of John Snow, and nothing at all by Budd. Volumes II and III of Priestley's *Experiments and Observations* are missing. Karl Pearson and Raymond Crawford are poorly represented, and while Osler is allotted 60 entries, Clifford Allbutt is given only 5, and *Greek Medicine in Rome* is not included.

The works of Vesalius are the gems of this collection. Here Cushing far outstrips Osler, who first taught him how and where to buy them. Against Osler's 14 early editions of different works, Cushing has 41. It is sufficient to say that this collection is the basis of Cushing's monumental *Bio-bibliography* which Messrs. Schuman's have recently published.⁶

Prof. Fulton calls this catalogue an "experiment in bibliography." It is essentially a short-title catalogue. (In some few instances there appears to be doubt regarding the actual edition described.) Authors' names are given in the vernacular and punctuation is largely omitted. Though the student will have to go elsewhere for further particulars, the method used has certain very definite advantages, and cross-reference is greatly facilitated. Prof. Fulton and his co-workers are to be congratulated on the completion of their long task, the publishers on the production of a pleasing and easily handled volume, and Yale University on the acquisition of a personal library of great distinction and importance.

PEPPYS AND ALCOHOLISM

Having recently made a study of venereal diseases in Pepys's Diary¹ (see *Journal*, 1944, 1, 298), Dr. J. D. Rolleston has made a similar inquiry concerning alcoholism.²

In the seventeenth century, and particularly during the Restoration, alcoholism was prevalent in all classes of society from the King downwards. Of special interest was the case of Pepys himself, who, after being an alcoholic subject, became, if not a complete abstainer, a very moderate drinker, and played an important part in the campaign against drunkenness in the Royal Navy, in which it was rampant. Total abstainers in those days were exceptional. Such a one was Mr. Prynne, who "at a great dinner in good company would not drink any health, even not the King's, but sat down with his hat on, but nobody took any notice of him at all." Apart from the King's Proclamation against drinking, swearing, and debauchery issued in the first year of his reign, Charles II was far from showing any opposition to inebriety, but was remarkably lenient towards the scandalous drunkards in his Court. A similar view was held by Prince Rupert, who on the occasion of a man being dismissed from his office of boatswain for drunkenness exclaimed, "God dam me, if they turn out every man that will be drunk, they must turn out all the commanders in the fleet. What is the matter if he be drunk, so when he comes to fight he do his work? At least let him be punished for his drunkenness, and not put out of his command presently."

As he had shown in his previous paper on Pepys, Dr. Rolleston remarked that several explanations had been offered for his numerous amorous escapades, the account of which had been more or less concealed by Victorian editors; but as many of his erotic adventures took place in ale houses, it was not improbable that alcohol was responsible to some extent for their occurrence.

Apart from chewing roll tobacco as a prophylactic against plague Pepys does not appear ever to have made any use of tobacco or other narcotic, but on one occasion he protested to the Commissioners of the Admiralty on "the incorrigible liberty found among workmen and watchmen taking tobacco."

Reports of Societies

THIOURACIL FOR HYPERTHYROIDISM

At a recent meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland Dr. L. K. MALLEY, in a paper on thiouracil in the treatment of thyrotoxicosis, observed that the toxic reactions from thiourea and thiouracil included agranulocytosis, increase in the size of the goitre, leucopenia, and dermatitis. He gave an account of three patients suffering from Graves's disease treated with thiouracil.

The first, a single woman aged 55, had no visible or palpable thyroid enlargement, but the pulse rate was 110, there was auricular fibrillation, the B.M.R. was +55%, and the blood cholesterol was 69 mg. per 100 c.cm. She was given an initial test dose of 0.2 g. of thiouracil, followed by 0.2 g. thrice daily for three days, the dose being then increased to 1.2 g. daily. After two weeks the B.M.R. fell to +13% and there was improvement in symptoms. A maintenance dose of 0.2 g. was determined, but on the thirty-fifth day of treatment signs of mild myxoedema appeared, the B.M.R. was -34%, and the blood cholesterol 248 mg. per 100 c.cm. Thiouracil was now given in a dose of 0.2 g. every fourth day. After eleven weeks of treatment the patient felt quite well; all symptoms of hyperthyroidism had disappeared; the pulse rate was 72 and now regular after a course of quinidine; she had gained 19 lb. in weight; and the B.M.R. was -7%. In the fourth month of treatment a moderate enlargement of the thyroid gland was noted.

The second patient, a married woman aged 33, had received preliminary treatment with Lugol's solution and the B.M.R. had fallen from +80% to +45%, but clinical evidence of hyperthyroidism persisted. Treatment with thiouracil resulted in a fall in the B.M.R. to +17% in three weeks and +3% in seven weeks. Exophthalmos and the goitre were unaffected, but all symptoms disappeared, and the pulse rate was reduced to 72. In the third patient, a man aged 38, treatment was discontinued on the third day owing to leucopenia (4,550 per c.mm.) and reduction of the granulocytes to 39%.

From a study of the literature and from a brief personal experience with thiouracil Dr. Malley concluded that it should be used with caution and only under properly controlled conditions, with frequent estimations of the basal metabolic rate and leucocyte and differential blood counts. Release of the drug for general use was premature. For the present its use

should be restricted to the pre-operative preparation of patients awaiting thyroidectomy, to those with persistent thyrotoxicosis after operation, in juvenile cases, and in the few cases in which operation was refused or considered inadvisable.

The PRESIDENT thought evidence showed that some cases were resistant to this drug. Dr. D. K. O'DONOVAN advocated giving a minute dose first and then steadily increasing it. Thiouracil sometimes produced an irritating nettle-rash; some of the preparations were nauseating and might cause diarrhoea and vomiting; the least toxic preparation, he thought, was methylthiouracil. Dr. T. M. KAVANAGH mentioned the case of a female child aged 2½ with toxic goitre, who did not improve on Lugol's solution. Two surgeons were doubtful about operation, so she was eventually put on thiouracil. After 3 weeks' treatment her white cells showed a small diminution and the gland itself was now smaller; she had put on weight. Graves's disease was very rare in childhood, and rarer in boys than in girls. A case had been reported in a boy of 2½ years, and in a female infant of 1 year.

Five Cases of Familial Paresis

Dr. MORGAN CROWE read a communication entitled "Familial Spastic Paresis with Strabismus." He chose this to describe the presence of squint in four and weakness with spasticity of the limbs in the five children of a family. The births of the children, whose ages were 17, 16, 13, 11, and 7 years respectively, were normal; no instruments were used. Their present disabilities were noticed in early infancy and had shown no tendency to spread; otherwise there was nothing abnormal in their history. Their parents were in good health and did not suffer from any similar defect, nor could they recollect any associated condition among their relatives. The lower limbs of these children showed varying degrees of adduction deformity and weakness. This permitted three of them to move about in a slow shuffling manner, with a "scissors" type of gait; one could propel herself only by holding on to a chair or wall; the youngest, the most seriously affected, could not stand by herself. In each child muscle tone was spastic in the lower limbs; knee- and ankle-jerks were increased, together with ankle clonus; but in only one child could a definite plantar extensor response be elicited. Club-foot is present in two cases; it had existed in another child but was rectified by surgery. Different degrees of hypermetropia, with visual acuity of about 6/12, were present in each child and accompanied by well-marked squint in four. Sensation generally, and the upper limbs, were normal; while mentally they were about two years behind the average for their age.

The condition would seem to be a modified form of cerebral diplegia and might perhaps be described as a spastic paraplegia or Little's disease; but the considerable degree of voluntary power in the legs of three of the children made paresis a more descriptive term. The loss of power, with evidence of upper motor neurone involvement and retention of sensation, seemed to negative any other diagnosis. The blood Wassermann reaction of parents and children was negative. The occurrence of the five cases in this family seemed to rule out infection, trauma, prematurity, or any abnormality associated with birth as the cause, for it was unlikely that any one of these conditions could have been present on each occasion. A failure of development, or a degeneration of motor cells or pyramidal fibres, would best explain the symptoms and signs. Photographs illustrating the defects were shown.

At a recent meeting of the Midland Tuberculosis Group of the Society of Medical Officers of Health Dr. George Jessel, a consultant tuberculosis officer to the Lancashire C.C., pointed out that the dispensary was the pivot of the tuberculosis work, which should be run by specialists in chest diseases, who should be paid as such. Improvement was required in buildings, general institutional and x-ray facilities, and in the co-operation with other specialists, as well as more efficiency in the environmental work. Policy and progress were dependent upon administrative officers who were often far from expert on the subject; fortunately many M.O.s.H. were now progressive. In discussing the White Paper it was agreed that the revision of boundaries and the enlargement of areas would help to ensure a uniform service of high quality. It was important, however, that the clinical and environmental aspects must not be dissociated, as tuberculosis is a public health service.

Correspondence

Operations on Infants as Out-patients

SIR,—I see from your correspondence columns (K. F. Pollaczek, June 3, p. 764) that there is a tentative suggestion about the wisdom of operating for hernia in young children as out-patients. Forty-odd years ago I was impelled to adopt this plan because of the very limited accommodation for infants and young children in the Newcastle-upon-Tyne Royal Infirmary at that time. A not inconsiderable and developing experience subsequently taught me that it is perfectly safe to undertake most operations that are likely to be necessary up to about 5 years of age as out-patients. Of course older children can be treated in the same way, but after 5 there is not the same necessity, for at times of great pressure such children can be accommodated among adults with little upset to either. For years now I have sent infants home on the day of operation carried out for all varieties of hernia, for umbilical fistula, even when it has been necessary to resect and anastomose bowel, for acute intussusception, and for other abdominal emergencies like the occasional acute appendicitis in the very young. When I was doing a considerable number of cleft-palate operations, cases in which the anomaly was limited to the soft palate or little more were nearly all done during the first twelve months, and the patients were sent home the same afternoon. I believe that in most cases these little ones have a better chance if dealt with in this way, for they go back to an environment to which they are accustomed, and, at least in normal times, they receive the undivided attention of persons with whom they are thoroughly familiar.

Of course it must be understood that these patients were not treated in any haphazard way. Cases which were not emergencies were always previously seen and examined and the proposed course explained to the parent. On the day fixed for operation they were brought to the day-room of the ward two or three hours before in order that they might receive the essential preparation and so that we could be sure the stomach was not overloaded by the time they reached the table. Emergencies had to be seen and dealt with more or less off the street, though if considered to be an advantage the necessary delay was arranged.

The actual operations were nearly always carried out in the regular operating theatres on the daily list. Except for a short period when trying out spinal anaesthesia and the very occasional cases where local infiltration anaesthesia was employed, general inhalation anaesthesia was used, either the A.C.E. mixture, open ether, or chloroform, and in that order. No premedication of any sort was employed. The children went back to the ward day-rooms until they had safely recovered from the anaesthetic and it was clear there were no immediate complications. As a rule they left in their mothers' arms, and mothers were told that if there was the slightest anxiety they were to be brought back to the hospital at any time of day or night. One miserable little infant, a cretin, died after circumcision, but that was due to haemorrhage aggravated by a tight bandage behind the corona.

Among the large number of other cases I can remember only one that was returned, and that was for the treatment of haemorrhage after a cleft-palate operation, the child recovering. Occasionally mothers brought the child back the next day or within the next few days because it would not settle or the dressings had slipped or for some other reason, but, on the whole, the results were most satisfactory. Here I might mention that dressings ought to be very carefully applied and bandaged well beyond the area. For years I have used anchored dressings tied on with a stitch passed through the skin as described and recommended by the late Sir John Lynn Thomas of Cardiff. In the first instance this practice of out-patient operating was a matter of expediency due to bed shortage, but it soon developed into an accepted routine, which I have no hesitation in recommending.—I am, etc.,

G. GREY TURNER,
Professor of Surgery.

British Postgraduate Medical School, W.12.

The Term "Blast"

SIR.—After this war there will be a spate of statistics on the various body injuries peculiar to warfare. This letter is a plea that the influence of fashion on diagnosis may be taken into account. Earlier in the war "blast" was a fashionable diagnosis. I once had the pleasure of meeting a medical officer who had seen over 100 instances of this interesting condition. In an experience of over 2,000 casualties, many of whom had been in a closed compartment with a bursting bomb or torpedo, I have only once made a diagnosis of blast lung; necropsy showed him to have his bronchioles choked with sand and mud. An officer with a diagnosis of blast lung has been transferred under my care recently, and radiography showed him to have a fractured skull vault, a crush fracture of the first lumbar vertebra, many fractured ribs, and a haemopneumothorax on each side. Nevertheless he is down on "someone's records as "blast." Is it possible that blast is commoner among sheep and goats than among men?—I am, etc.,

FRANK STABLER,
Surgeon Commander, R.N.V.R.

Thiouracil and the G.P.

SIR.—I have followed the reports of thiouracil with great interest, particularly the account in the *Journal* of the discussion at the Royal Society of Medicine (June 24, p. 852). There are, however, two somewhat disturbing opinions expressed by the specialists who took part in this discussion. It is reported that Mr. Cecil A. Joll "hoped that treatment with thiouracil would be allowed only under strict control, and that manufacturers would not release this powerful and dangerous drug to all and sundry." Dr. S. L. Simpson appears to support this by expressing the opinion "that it was a potentially dangerous drug and at present should be used only by those who had specialized knowledge and were capable of observing their cases closely." If it is the opinion of these speakers that thiouracil should be regarded as a dangerous drug whose sale is to be limited strictly to members of the medical profession, then I am in complete agreement with them. But these two passages which I have quoted, when taken with their context, would imply that the sale and use of these drugs should be further restricted to the élite among the specialists, and that the great majority of the medical profession should be placed on the same side of the fence as the layman, who is unable to obtain the drug except on a medical prescription.

Now if I have correctly interpreted these remarks, certain fundamental questions are raised. Who, for instance, is to decide who is a specialist who may safely be entrusted with supplies of thiouracil? Are the manufacturers to have lists of doctors whom they may supply, and who is to provide these lists? It possibly may not have occurred to the pundits of the Royal Society of Medicine that even general practitioners sometimes take a keen interest in their cases and are eager to follow the latest developments of research, particularly when there is afforded so powerful a remedy for a hitherto intractable disease. Surely the only criterion of trustworthiness for the use of these drugs must be the practitioner's own conscience. A man who has kept himself in touch with such information and reports as are available, and has carefully studied the needs of his individual patients, may safely be left to decide whether he is in a position to use these new remedies without endangering the health of those who trust him.—I am, etc.,

D. STANLEY-JONES.

Hayle, Cornwall.

Chemotherapy in Otitis Media

SIR.—Mr. Steele's letter in your issue of June 24 (p. 854) emphasizes a very important point. If sulphonamide therapy is withheld in the early stages of otitis media we shall have many more mastoid infections. I have seen many "threatened mastoids" resolve completely under adequate chemotherapy, but, as Mr. Steele points out, it is the general practitioner who sees these cases in their early stages, in which their treatment is so important.

I think the general practitioner of to-day is very alive to the importance of this early treatment. Of course this does not mean that every case of P.U.O. should be put on sulphonamide therapy, but once a diagnosis of acute otitis media is made

this treatment should be started. Our admissions of acute mastoiditis are only about a third of those in pre-war days, and I venture to think they will even get less when early adequate treatment is universally given—I am, etc.

T. J. JOHNSON

Recurrent Laryngeal Paralysis complicating Infective Hepatitis

SIR—I was most interested to read the article on the nervous complications of infective hepatitis by Dr F. G. L. Lescher.

Some time ago I treated a lance-corporal with a moderately severe infective hepatitis with jaundice, during the course of which his voice became husky, and the ENT specialist, after reporting nil abnormal on the first complete examination of the patient, reported a commencing paralysis of the left recurrent laryngeal nerve. The otologist said that the paralysis really began before his eyes. The paralysis became complete and then made a very gradual recovery over a period of months. There were no other neurological signs or symptoms. There was no possibility of diphtheria, either cutaneous (facial, nasal, laryngeal, or cryptic). Numerous investigations (such as blood sedimentation rate (normal), Wassermann reaction (negative), complete blood counts, x-rays (root of neck, chest, barium swallow, etc.) etc. were carried out and repeated.

No therapeutic agents used in the treatment of the infective hepatitis could have been responsible for the paralysis of the recurrent laryngeal nerve. Such treatment consisted of high protein, high carbohydrate, high vitamin (including massive ascorbic acid therapy and "multivite" tablets) and fat free diet, sod bicarb 5j thrice daily after food and mag sulph in the morning when necessary.

As I was unable to demonstrate a known cause for the paralysis of the left recurrent laryngeal nerve, which occurred during the course of a moderately severe attack of infective hepatitis in a subject free from syphilis, I felt justified in regarding the neurological lesion as a complication of infective hepatitis from which the patient was suffering—I am, etc.

Major R.A.M.C., Medical Specialist, M.E.F.

Sodium Pentothal in Nasal Operations

SIR—All of us will be very grateful for Dr Sandiford's advice (June 17, p. 826) on the administration of sodium pentothal.

In China, as a missionary, I did all the nasal operations under twilight sleep and cocaine, and continued with this method on returning to England until sodium evipan was introduced. Then I resorted to sodium evipan, only to turn to sodium pentothal as soon as it was on the market. It is indeed a wonderful anaesthetic. A few days ago I did a septum, Caldwell-Luc and a Sluder's sphenoidectomy under this anaesthetic and then, as there was no pus, only thickened polypoid membrane in the nasal sinuses, I dissected out the tonsils while the patient was under the sodium pentothal, and it proved to be a perfect anaesthetic for this extensive operation. The pre-anaesthetic was morphine 1/4 gr., scopolamine 1/150 gr., atropine 1/100 gr., and oxygen given during the whole operation through an intrapharyngeal tube.

I have had only one death among the many patients operated on in two hospitals and two private nursing homes. This was a private patient, a woman, and while the pentothal was being administered I painted the face with industrial spirit. The patient ceased to breathe, and in spite of artificial respiration she died almost at once, before I had time to arrange the towels or commence operation. The pre-anaesthetic in this case was omopon 1/3 gr., scopolamine 1/100 gr., and atropine 1/100 gr. The anaesthetist, who is highly skilled and has administered many anaesthetics for me, said the death was due to my applying the industrial spirit while he was inducing anaesthesia, so now my first rule is never to go near the patient until he is fully under the anaesthetic, applying cocaine in the bedroom before the patient is carried to the theatre. My second rule is to have picrotoxin in every theatre in which I operate, as unfortunately there was no picrotoxin in the theatre on that fatal day, and I consider the drug far superior to coramine or oxygen in such a case. My usual

anaesthetist administers oxygen during the whole operation inserting a small metal mouth tube before commencing the anaesthetic, and then he inserts a curved rubber tube attached to a metal tube into the pharynx, through which he administers oxygen.

To sum up in nasal operations safety is produced by (1) never touching the patient until the anaesthetist says the patient is not only asleep but also well under the anaesthetic, (2) never operating without having picrotoxin at hand for intravenous injection, (3) having a tube in the pharynx for the continuous administration of oxygen, which renders the second safeguard unnecessary except for my own peace of mind, and (4) giving a minimum dose of morphine or omopon—i.e. 1/6 or 1/8 gr. never 1/4 gr.—as I believe a contributory cause of death in my one fatal case was the administration of too large a dose of omopon.

These extra notes might be added to Dr Sandiford's most helpful advice—I am, etc.

Harrow, etc.

W. S. THACKER NEVILLE

Ether and the Oxford Vaporizer

SIR—I was sorry to see a letter in your correspondence columns deprecating the use of ether in the Oxford vaporizer. At the Wellhouse Hospital, Barnet, we have used this machine for some considerable time for the anaesthetization of many hazardous cases and our results have been quite strikingly successful. In case some practitioners should feel that the use of ether is out of date and that they are not doing their best for their patients I should like to record a recent case.

A man aged 40 was admitted as an air raid casualty. He had received blast from a bomb on his left side and the whole of the left side of his body was peppered with innumerable fragments of glass, some of which had passed into the abdomen. It was felt that he was suffering from intraperitoneal haemorrhage as well as very severe shock. Ten days previously he had undergone the operation for artificial pneumothorax for tuberculosis on his right lung, the one remaining lung being on the blasted side. It became evident that to save his life an exploratory laparotomy must be done.

A request was made to the surgeon to use local anaesthesia but he requested ether through the Oxford inhaler, and I agreed to administer it. He was given endotracheal oxygen-ether from the Oxford vaporizer. The spleen was found ruptured and was removed but the haemorrhage continued, so the surgeon had to make a thorough exploration. In the mesentery numerous branches of superior mesenteric artery were found bleeding and a number of vessels had to be tied. There were eleven perforations in the jejunum, and it was obvious that the intestine would have to be resected to include the damaged mesentery, and this was done with end-to-end and precautionary side-to-side anastomosis. The abdomen was closed after an operation lasting one hour and forty five minutes from start of anaesthesia to completion. The patient made swift and uncomplicated recovery. There was no post-operative chest or any other kind of trouble.

Now this is only one of the many difficult and dangerous cases which come our way with frequency. I believe that ether is still the best anaesthetic for these cases and that the Oxford vaporizer is the best way of administering ether—I am, etc.

New Barnet.

JOHN ELAM

Pentothal Anaesthesia

SIR—I have read with great interest the letters of Drs F. W. Roberts and H. B. C. Sandiford (June 17, p. 825) on the administration of pentothal. An ardent pentothal "fan," I have used it very extensively indeed since it came on the market, and have never yet experienced a fatality following its use. I attribute this to the fact that I have a very lively respect for this powerful anaesthetic agent. To avoid fatalities I would insist on the following.

1. It should be administered by experienced anaesthetists only. No rank-and-file medical officer, in fairness to the safety of the patient, should be allowed to use this powerful—dangerous, if you like—drug.

2. It should never be administered to casualties suffering from severe haemorrhage or prolonged exposure.

3. It should never be used in toxic or debilitated cases.

4. It should be used with the very greatest care following injection of morphine, especially after repeated injections. The respiratory depression caused by pentothal adds to and accentuates the similar action of the morphine, leading in many cases to some anxiety.

5. The solution of pentothal should never exceed 5%; the more serious the case the weaker the solution.

6. An assistant should *always* be at hand to see that no occlusion, partial or otherwise, of the air passage occurs; *the jaw must be held up*, otherwise severe spasm may occur.

7. Don't hurry anaesthesia by rapid administration; 2 to 3 c.cm. in the first minute—no quicker; subsequent administration should be slower.

8. When the patient is surgically anaesthetized stop the administration, and only when necessary continue the injection 1 c.cm. at a time as required.

9. The following should always be at hand: oxygen, picROTOXIN, ephedrine, and coramine; and, needless to say, the doctor conducting the anaesthetic should know how and when to use them.

The dose required to produce anaesthesia varies enormously; hence the required experience. To illustrate this wide range of dosage I cite three cases of my own.

1. M., aged 17. Operation, extraction of four teeth. 1½ g. only just produced the necessary anaesthesia.

2. M., aged 37. Operation, nasal septum. Premedication 1/100 gr. atropine and 1/4 gr. morphine. 2 g. required to produce anaesthesia. Respirations and pulse normal. Twenty-five minutes after the injection the patient was talking quite normally.

3. F., aged 34. Previous history of tuberculosis but no actual lesion. Operation, hysterectomy for fibroids. Premedication 1/100 gr. atropine and 1/4 gr. morphine. Pentothal requested, to be followed by N₂O and O. One large ampoule of pentothal (1 g.) dissolved in 20 c.cm. water. Of this 7 c.cm. produced surgical anaesthesia. Fifteen minutes later patient started to move; 3 further c.cm. in three minutes was injected. Five minutes later respirations stopped, pulse feeble. The syringe was withdrawn, gentle artificial respiration and continuous oxygen were started. Two c.cm. picROTOXIN intravenously and coramine intramuscularly were given. The operation was so far advanced that it had to be completed. After fifteen minutes respiration restarted and pulse very much improved. The operation was finished successfully, and after four hours the patient was fully awake and her condition was good. The whole operation—lasting 45 minutes—was performed on 1/2 g. of pentothal and the premedication.

Even the most experienced anaesthetist, exercising the greatest care and vigilance, will get, when he least expects it, a reminder that pentothal anaesthesia is not always "child's play."—I am, etc.,

OSWALD J. MURPHY,

Dublin.

Hon. Anaesthetist, St. Vincent's Hospital.

Metatarsalgia

SIR,—As a unit medical officer in the R.A.F. I see numerous cases of painful feet, and I was particularly interested in the letter by Mr. A. C. Fisher (May 27, p. 731) on the subject of metatarsalgia.

The term "metatarsalgia" may be applied to several conditions, but the one to which Mr. Fisher refers is clearly the static or relaxation variety which follows unaccustomed standing or walking (particularly the former, in my experience), and I think few will disagree with his statement that a metatarsal bar is singularly ineffective in its treatment. I cannot agree, however, that the existence of an anterior transverse arch of the foot is a piece of anatomical fiction, for, although flattened at every step, it is there to be seen in the normal foot, and is in fact restored when fallen by the very exercises described by Mr. Fisher. Moreover, the arch can be exaggerated by voluntary activity of the muscles of the foot. Surely, too, the large thick callosities so often seen beneath the head of the third metatarsal are sound evidence that in this condition more pressure than normal is being borne at this site—i.e., the arch has fallen.

However, the main point of this letter is to support the treatment which Mr. Fisher describes and to stress the importance of foot exercises in the prevention of painful feet. Being convinced from the effect of rest, and from the history of prolonged standing almost invariably given, that the condition results from muscular fatigue, I keep the patient in bed for two days before commencing the exercises with the patient seated and his feet on the floor. As the power of flexion of the toes increases the feet can be made, by alternate contraction and relaxation of the muscles, to crawl forwards along the floor in caterpillar fashion. This exercise is continued at first for five minutes and later ten minutes every hour until the patient can pick up a handkerchief with his foot. In the

early stage hyperhidrosis of the feet is usual, and much relief is given by contrast foot-baths twice or thrice daily. Before discharge it is impressed on the patient, as Mr. Fisher points out, that he must continue the exercises whenever he is standing, alternating them with rocking slowly up and down on the toes.

Having experienced this condition personally, I can confidently whole-heartedly the pain which it produces and the mark and lasting relief afforded by redeveloping the muscles. I am, etc.,

A. STANDEVEN, F.R.C.S. Ed.,
Fl. Licent. R.A.F.V.R.

Cold Agglutinins

SIR,—In your leading article on cold agglutinins (July p. 16) you state that "an abnormally high titre of cold agglutinins has been found in the serum in a variety of diseases but most constantly in atypical (virus) pneumonia and trypanosomiasis, in both of which diseases the reaction is of diagnostic value." It may be of some interest to state that some weeks ago I examined six samples of serum, sent me by the courtesy of the Director of Medical Services, Uganda for cold agglutinins. The sera were separated from the patient cells before being dispatched, and it was therefore possible to test the former against Group O cells. The methods I used were similar to those given by Turner *et al.* (*Lancet* 1943, 1, 765), and my results were completely negative. A few cases were proved ones of sleeping sickness, and the sera were tested for sterility on arrival.

Obviously no conclusions can be drawn from such a small number of cases, but it may be that haemautoagglutination in this disease is not so common as some authors and textbooks would lead one to believe.—I am, etc.,

Godalming.

KENNETH FROOME.

Estimation of Dental Caries

SIR,—There are several criticisms which could be made of the report on the improved dentition of London school-children (June 24, p. 837), but I wish to confine myself to one point only—namely, the method of examination adopted for classification of degrees of caries. It is absolutely impossible to gauge the extent of carious destruction with a mirror and probe examination only, and it is frequently impossible to detect interstitial caries except with x-ray films. I do not think that any dentist of experience who has consistently used x-ray films to check his routine examinations would dispute this statement.

Where caries has destroyed a large part of the crown the condition is clear, but Lady Mellanby seems unaware of the fact that a tooth may show only a slight stain, and, on drilling, it may be found that the caries has penetrated to the pulp tissue.

Dental research on the lines adopted by Lady Mellanby should only be undertaken if it is realized that: (a) x-ray examinations must be made; (b) every tooth showing signs of caries must be drilled to ascertain the extent of penetration of the caries. If it is not possible to conduct the examinations in this way then the research should not be undertaken.—I am, etc.,

Oxford.

DOROTHY SMITH.

Ophthalmologist and Optician

SIR,—I have followed with interest the recent correspondence on the status of the sight-testing optician, and feel that there are important points of view which have not yet been stated. I am one of the small handful of men who, before entering medicine and practising ophthalmic surgery, were opticians, and who should perhaps be in a position to view the question from a different angle from the purely medical and optical factions. First, it must be realized that the sight-testing optician is essentially a product of the evolution of our present social system, and he has developed in response to a public demand for a retailer of spectacles who could at the same time advise as to the nature of the lenses required. In fulfilling this demand the optician has set himself voluntary, but at the same time fairly high, educational standards to ensure that the service he renders shall be of a definite value, and not only does he aim at becoming proficient in refraction but also at being capable in the detection of such abnormal conditions as should be referred to a medical man.

Secondly, it must, I think, be admitted by the medical profession that earlier in this century, during the period in which big development in the optical profession took place, the combined facilities offered by the ophthalmic surgeon and the dispensing optician were both inadequate and too expensive for the community as a whole.

Thirdly, even to-day, if all refraction work of the community was undertaken by the ophthalmic surgeon he would be grossly overworked and unable to give proper attention to what should be his chief activity—the care of the diseased eye. Moreover, if all refraction was done by medical men the proportion of ophthalmic work which might be labelled ophthalmic medicine and surgery would be very small giving rise to the alternative of (a) The employment of skilled surgeons with highly specialized knowledge in the mechanical measurement of errors in healthy eyes (b) The creation of a body of medical men to be engaged solely in refraction and the reference of pathological conditions to his more skilled colleague. My comments on this are (1) it would result in complete waste of medical training, knowledge, and skill that could be better employed in some other branch of medicine. (2) the optician properly trained in clinical methods could do the work.

There are I know, many in the medical profession who regard the sight testing optician as an evil. To them I would suggest that he must be regarded as a necessary evil and that all possible must be done to minimize any harm which they consider he might do. The means for this are in my opinion obvious. Improved educational facilities must be afforded the optician, and this can be done both by the medical profession as a whole and by its members individually. For myself, I owe my initiation into ophthalmology to those optical organizations which instituted examinations for which I originally studied. I am indebted to the optical profession for a wide experience in refraction and the recognition of ocular disease, and I have to thank an income derived from optics for my medical training. To pay those debts I consider it a moral obligation to further in any way possible especially in the field of education the cause of the optician.

I have recently seen a document purporting to quote a letter from an ophthalmic surgeon who was at one time like myself an optician. This gentleman has, apparently, nothing good to say for the optician, optical organizations, or the requirements and facilities of optical education, and I cannot but feel how much better it would be for him to offer his criticism in a constructive and helpful manner to the optical profession to which I am sure he owes his original interest in ophthalmology.

I was recently consulted by the Joint Advisory Committee to the Optical Profession (which represents some half-dozen organizations with I believe a total membership of over 8,000) regarding the future of optical education. Would it not be to the benefit of the community as well as the medical and optical professions if that committee had the advantage of the advice co-operation and practical help of leading and truly representative members of the ophthalmic section of the medical profession?—I am, etc.,

London W 1

GEOFFREY EBBAGE.

A National Pathological Service

SIR—It is indeed an interesting article that you published in your issue of June 10 on a national pathological service. It is very significant of the times in which we are living that a self-constituted group of leading pathologists should thus gratuitously undertake what even inveterate Governmental planners have not carried out.

There is abroad, not only in the medical profession but throughout the world, an entirely erroneous idea that the sorrows of the universe can be obviated by man-made plans. That most of these plans must be products of the essentially finite mind of man appears never to have been considered. Any hastily conceived plan or written scheme must necessarily be non-elastic and entail a measure of compulsion, more or less rigid, on the public and professions concerned. This present eruption of planning is surely the outward sign of a disease of the "body politic." There appears to be no method of assessing how widespread is the infection without recourse to the medium of publicity.

The plan put forward appears to partake of the full virulence of any and all of the plans for the compulsion of the public. Unfortunately the fact that these medical planners are prominent in their profession may blind the eyes of the rest of their colleagues to the essential unsoundness of some of their suggestions which while they embody some very useful and desirable points also indicate a desire to meddle with matters entirely outside their scope.

It is worthy of comment that the 'planners' are all largely of the academic type. That they should advocate the correlation of pathology under their own aegis is perhaps not difficult to understand. Unfortunately there must be a suspicion that these authors aspire to be the constituent members of the Gestapo-direction of the new plan. An indication of their outlook is the naive suggestion that coroners' work should come under their protection and care. That coroners' work is in the hands of general practitioners is not a fact. Most coroners' work is in the hands of specialized pathologists and more and more is coming into their hands. Those concerned with this subject realize that there is so much coroners' work that it would not be fair for senior hospital pathologists to be expected to undertake it. Crime quite frequently does come to light during the performance of routine coroners' necropsies. Is it suggested when this occurs that the senior hospital pathologist "should drop the inquiry and hand it over to the medico-legal officials, or what? It is perhaps worthy of consideration that these ardent planners have not condescended to ascertain facts nor so far as can be seen to ascertain the views of those engaged in coroners' morbid anatomical work, neither have they, apparently, made any approach to the Coroners' Society.—We are, etc.

E. E. HEANEY
H. M. STANLEY TURNER,
DAVID HALER,
Guildford Practitioners' Group

Medical Training

SIR—Criticism of the medical curriculum is a perennial subject, and doubtless there is something to be said for improvement in the courses of study for medical students, but one wonders if the wholesale criticism so often indulged in is not too severe. The test of anything is how it works when put into practice and one definite test of the medical curriculum is found in seeking to apply in primitive conditions what has been taught in student days, for in primitive conditions one has to start from the foundation by gathering together the required equipment, and even to erect the necessary buildings for carrying out medical practice as inculcated by our teachers.

For almost twenty years I have been in medical work in the African bush and veld, and the experience gained has made me grateful to professors, lecturers and the writers of medical textbooks. The chief regret has been that more was not made of student days. The daily dispensary has remained of absorbing interest. During the first five years after graduating there was hardly a day in which one did not encounter something that had been heard of or read about but not seen previously. How thankful one has been for the many hints garnered from teaching surgeons and physicians, helps which could be recalled with pleasure to oneself and profit to patients. So much has this been so that the conviction has grown that every scrap of teaching and experience can be made use of when out in the wilds on one's own.

For example, on one occasion I was confronted in the bush by a man with a dislocated shoulder, brought by a crowd of raw Africans. No anaesthetic was immediately available and without it there was failure in applying the standard Kocher's method for reduction. There seemed nothing for it but to have the patient taken by canoe to our hospital, which was twenty miles away. Then there flashed across the memory an afternoon in a surgical dispensary of a Glasgow infirmary, when a surgeon dramatically reduced a shoulder dislocation by laying the patient on the floor, standing on a chair and using the muscles of the patient's arm by pulling steadily on them for three minutes then jumping over the patient's body and letting the arm drop in the passing. This method was hopefully attempted in front of the gaping crowd, and, coming off first attempt, rejoiced them because it so much savoured of the magic which African hearts love. That Glasgow surgeon will ever be gratefully remembered by his student. Such incidents could be multiplied indefinitely.

Thousands of patients are helped every year at the outposts of Empire by the application of the teaching which was given

by those whose work is so much criticized. If advice may be given to students, it would be along the line of absorbing all the knowledge they can from their teachers and textbooks. Such instruction, along with the help given by trained European nurses, is the biggest factor in postgraduate work abroad. Even the preliminary sciences should be studied gladly, for they provide a good base. The teaching of anatomy is most often the butt for criticism. Looking back one is not aggrieved at the amount of detail which had to be assimilated, rather the regret is that so much of what was taught has been allowed to slip the memory.

Professors, medical curriculum, British Medical Association, medical textbooks—all come in for sharp criticism. Professors are not always interesting lecturers, we know, but we are indebted to them, and their fairness in examinations is remembered with gratitude. It may be possible to improve the medical curriculum, but it is to be remembered that it has been built up after much thought, trial, and error. The British Medical Association may have its faults, since it is composed of human beings, but medical life and practice in the backwoods would lose much if the pages of the *British Medical Journal* were not available for perusal. Medical writers may give us dry books at times, but their compact volumes guide us out of many difficulties. One colleague, who built up a successful surgical practice, while operating used in his early days to have a number of books stuck up in the operating theatre, all open at the appropriate pages ready for reference in emergency, and he would have repudiated the suggestion of a critic to burn such tomes.

To criticize is easy, cheap, and destructive; but to lecture, demonstrate, and write is difficult, costly, and constructive. Let us give honour where honour is due.—I am, etc.,

Scottish Livingstone Hospital, Molepolole, S. Africa. P. M. SHEPHERD.

Character and Personality in the Medical Student

SIR,—Evolution has shown that in a self-sufficient community we have to have our dustmen as well as our doctors. The dustman is just as much of a specialist in his job as the doctor is in his and just as important. Heredity and environment are by no means negligible factors in a child's upbringing, and therefore we tend to look for our future dustmen among the children of dustmen and our future doctors among the children of doctors. Presumably when we painted ourselves with woad and lived in caves we were approximately equal in wealth, eminence, and social position. As time went on differences in social position due to differences in character and ingenuity developed, until at the present time we find ourselves members of a very complex community with its many specialized jobs and many gradations of wealth. This evolution was gradual, and inevitable.

It is well to remember that legislation should always be enacted for the good of the majority and not for the good of a few exceptional cases. To illustrate: legally it is criminal to induce an abortion except for certain specified reasons, and in the exceptional case of a girl being raped and becoming pregnant the law offers no remedy. The Planning Committee of the College of Physicians takes the opposite view to this legal axiom, and for the sake of the few exceptional cases of dustmen's children wanting to become doctors throws open the portals of medicine to everyone.

I congratulate most warmly Dr. E. D. Broster on his courageous letter (May 27, p. 729). I feel it is high time that we paid tribute to our men of letters and our great industrialists instead of sneering at them in a manner calculated to gain momentary favour for ourselves in the eyes of our dustmen—a habit that is becoming far too fashionable nowadays. Let us realize that, in general, the possession of wealth, intelligence, and individualism is not a thing to despise, and that through centuries of evolution the doctor has achieved a certain social standing with a certain reputation for manners, courtesy, and sympathy which make him as acceptable in the tenements of the poor as in the palaces of kings.

In view of the foregoing I find it hard to appreciate the sentiments implied in Dr. H. E. Vickers's letter (June 17, p. 828), and wonder if he seriously asks us to put the clock back 2,000 years.—I am, etc.,

Menston, near Leeds.

R. JOHN GOURLAY.

Spanish Medicine

SIR,—It would be hard to compile a more misleading article than the one on Spanish medicine which appeared in your issue of June 17 (p. 820). Will you afford me space to correct two major absurdities which are representative of a constant recurring theme in the literature of modern amateur historians.

The first is a well-known myth about Michael Servetus. Your correspondent may have intended to deceive; I prefer to believe that he is ignorant either of the facts or of the plain meaning of his own words. However that may be, Servetus had no ecclesiastical music to face on account of his attack on Galen; nor did he fly from Catholic Spain to Geneva. He left Spain in 1529 as the secretary of the Emperor's confessor and spent the rest of his life wandering about Europe. His discovery of the lesser circulation was probably made at Paris, and, so far as is known, brought him neither ecclesiastical censure nor medical renown. He then wrote a book on theology, controverting a dogma which was dear to Calvin—the consubstantiality of the Father and Son in the Trinity. Calvin denounced him to the French Inquisition, from the prisons of which he escaped after a brief confinement, only to suffer death by burning at the hands of Calvin.

The second is summarized by your correspondent in a grandiloquent sentence: "The reason for this poverty of medical science . . . must surely be sought in the anachronistic survival of that spirit of authoritarianism which is the mortal enemy of experiment and discovery." For those of us who believe in the virtues of democracy and the vices of authoritarianism it would be nice if this were so, but, of course, it is nonsense. One could adduce countless examples, beginning with Galen (that ingenious experimenter who discovered the secretion of urine by the kidneys), to disprove this thesis; I shall content myself with three modern ones. (1) Both Pasteur (who lived and died a Catholic, by the way) and Claude Bernard received their first encouragement from Napoleon III, a free-thinking authoritarian. (2) The greatest advances in German medicine have all occurred under authoritarian regimes; the discovery of the antibacterial potency of sulphonamides by Domagk is only the latest example of a long series which stretch back to the beginning of the nineteenth century. (3) Pavlov commenced his great work under the Czars and finished it under the Bolsheviks. Stalin, who is probably the most convinced authoritarian of all time, liberally encourages medical research.

It would indeed be much easier to argue in favour of the exact opposite of your correspondent's thesis; but the clear truth is that medical advances are quite independent of political or ecclesiastical regimes. They depend largely on the wealth and education of the country concerned. Spain is poor and her people have had few opportunities of secondary and university education, because she has been ruled for 100 years by an oligarchy of more or less corrupt politicians who were more concerned to expropriate than to obey the Catholic Church.—I am, etc.,

Dublin.

T. W. T. DILLON.

Dr. Alexander Lipschutz, director of the department of experimental medicine of the National Health Service at Santiago, Chile, has been awarded the second \$2,000 prize given by Dr. Charles L. Mayer and administered by the National Science Fund of the National Academy of Sciences, New York. The prize was offered for an outstanding contribution made in 1943 to present-day knowledge of factors affecting the growth of animal cells with particular reference to human cancer. The recipient of the 1942 award was Dr. Charles Huggins, professor of surgery at the University of Chicago. During the last six years Dr. Lipschutz, together with the Chilean scientists working in his laboratory, has studied the fibromyomas of the uterus which can be induced in guinea-pigs by injecting certain sex hormones of the female. The growths closely resemble the fibromyomas ("fibroids") which occur in women during the childbearing period, and Dr. Lipschutz has shown that, like these they dwindle and vanish when the stimulation of the sex hormones is withdrawn, as happens after the menopause in women. He and his associates have sought means to prevent the occurrence and enlargement of the growths while the hormones are still acting, and recently they have found that some other hormones, from other organs, have this effect, as do also certain substances synthesized by chemists. The molecular configurations responsible for the influence of the antifibromatous agents are now under investigation.

Obituary

PROF. J. SHAW DUNN

Dr. A. PINEY writes:

May I pay a tribute to the memory of John Shaw Dunn, who held the chair of pathology in Birmingham when I was lecturer in pathology? The obituary notice in the *Journal* ignores the qualities of Shaw Dunn as a teacher and as a man. He was an excellent and lucid exponent of pathology, and everyone who attended his demonstrations in the post-mortem room was enthralled by his clarity. Admittedly, for a time after he started his work in Birmingham, both students and junior pathologists were very much in awe of his rather cold manner. It was not long, however, before he was described in the students' magazine as "a facultative humorist of the dry type"; and his personal popularity became so firmly established that there was much regret when he went to Manchester. Others who have worked with Shaw Dunn more recently than I can doubtless add much to our knowledge of him; but I feel strongly that the extreme honesty of mind, the care in the preparation of lectures, and the essential kindness and humour of this outstanding figure among modern pathologists should be emphasized.

Dr. WILLIAM HABGOOD, who died in retirement at Bourne-mouth on June 6, aged 81, was medical officer of health for Sutton, Surrey, from 1908 to 1934. He studied medicine at King's College Hospital, and after qualifying as M.R.C.S., L.R.C.P., and L.S.A. in the early 'eighties, took the Brussels M.D. degree in 1888, and the D.P.H. of the English Conjoint Board in 1893. Before his appointment at Sutton and Cheam Dr. Habgood had been assistant M.O.H. at Cardiff and at Nottingham and assistant school medical officer under the Surrey Education Committee. He joined the B.M.A. in 1887, was secretary of the Section of Psychology at the Annual Meeting of 1891, and vice-president of the Section of Medical Jurisprudence at the Aberdeen Meeting in 1914.

Dr. HILTA INES CHRISTINA MORLEY, with her husband, Stephen Charles Morley of the Nigerian Marine Department, has died 'by enemy action at sea.' Her maiden name was Pfister and she had a distinguished student career in the University of Western Australia, Perth, where she graduated B.A. (with first-class honours) in 1920, and in the University of Edinburgh, where she graduated M.B., Ch.B. (with first-class honours) in 1925. Dr. Morley had been lecturer in physiology at the University of Birmingham, medical officer to St. Alfege's Hospital, Greenwich, and senior house-surgeon to the Elsie Inglis Maternity Hospital, Edinburgh. She joined the B.M.A. in 1926 and took the D.P.H. of the Conjoint Board in London in 1931. Until lately she had lived at Cheltenham.

With the passing of JOSEPH WALKER, M.R.C.S., L.S.A., on June 18 at the ripe age of 93 years the Liverpool Division has lost a courtly Victorian physician. He first settled in the district at Kirkby in 1888, and in 1899 came to Bootle, where he practised for 40 years before retiring to Formby. He joined the B.M.A. in 1884 and quickly became interested in medical politics. He was Representative for Liverpool Division at six Annual Meetings, and had been chairman of the Division. He took a great deal of interest in the first National Health Insurance Act, and though he never joined the panel he was always ready to help those practitioners who wished to join; he served on the Bootle Insurance Committee for some years and went as a representative of the Bootle Local Medical and Panel Committee to the Annual Panel Conference. He also took a great interest in the Royal Medical Benevolent Fund, and for many years was honorary secretary for Bootle. In motoring he was one of the pioneers, and I well remember his De Dion single-cylinder car. He was an avid reader of his *Journal*, and whether it was an academic leading article or a medico-political point which affected the profession generally, he was as ready to discuss the one as he was to repudiate the other; his grasp of the essential point was great, and his judgment almost unerring and at times uncanny. To the younger generation of doctors he was most kind, always ready to help with sound, fatherly advice, tempered with a gentle humour that endeared him to all fellow practitioners and patients alike.—E. I. C.

Dr. JEAN GWENNETH BRABNER died by enemy action last month while on hospital duty. She was the elder daughter of Mr. and Mrs. W. W. Brabner of Harley, Loughton, Essex, and only entered the profession this year, qualifying as M.R.C.S., L.R.C.P., and joining the British Medical Association.

The death is announced at Sandgate, Kent, of Dr. WALTER DENBY, formerly of Bradford, aged 83. He graduated M.B., C.M. at the University of Edinburgh in 1887 and proceeded M.D. in 1898. After serving as house-surgeon at the Bradford Royal Infirmary he practised for 30 years in Great Horton Road, Bradford, and was senior surgeon to St. Catherine's Home for Cancer and Incurables. Dr. Denby joined the British Medical Association as long ago as 1888; he retired from work in 1924.

The Services

The announcement concerning Capt. R. Fletcher, R.A.M.C., published in a *Supplement to the London Gazette* dated April 6 and in the *Journal* of April 29 (p. 605) as mentioned in dispatches should have read Capt. (Temp. Major) R. T. Fletcher, R.A.M.C.

Owing to a printer's error the name of Wing Cmdr. G. B. Grayling, R.A.F.V.R., published in the *Journal* of July 1 (p. 29) as mentioned in dispatches, was incorrectly spelt.

CASUALTIES IN THE MEDICAL SERVICES

Capt. SAMUEL CHARLES HOLLAND HOOD was killed by enemy action in Normandy on July 13 at the age of 25, being struck by a mortar shell while actually attending to wounded. He received his education at Tonbridge School, Caius College, Cambridge, and the Middlesex Hospital. The final part of his clinical training was carried out at the Royal Hospital, Wolverhampton, and he obtained the Conjoint diplomas in 1942 and the M.B., B.Ch. the following year. Mr. R. Milnes Walker writes: After qualifying he held for a short time a resident post at the Hallam Hospital, West Bromwich, and was subsequently house-surgeon at Wolverhampton. While there he won the respect of all those who worked with him by his conscientious attention to his duties and the diligence with which he carried out his work. He was rapidly developing a sound critical judgment. His especial interest lay in the study of diseases of the chest, and he had hoped after the war to follow this up by further study of tuberculosis. While at Cambridge he was a member of the Cambridge University Scientific Expedition to North-East Greenland. His commanding officer writes in glowing terms of the exceptional way in which he carried out his work during the first difficult days in Normandy.

Wounded—Temp. Major F. L. Cane, War Subs. Capt. C. Moore, War Subs. Lieut. A. S. Smith, R.A.M.C.

Died of wounds—Capt. C. H. Blackham, R.A.M.C.

Reported prisoner of war—Capt. G. S. Hodge, R.A.M.C.

Universities and Colleges

UNIVERSITY OF BIRMINGHAM

At a Congregation on July 1 the following degrees were conferred:

HON. MD—H. Guy Dain, M.B., LL.D.
HON. M.Ch.W.—Warwick James OBE, FRCS.
F.R.M.B. Ch.B.—R. Asley, R. F. Baird, Kathleen J. Bee, Katharine N. Bentley, D. H. Blake, M. B. Chitheroe, Hilary B. J. Cooke, J. Cox, J. H. Cox, D. F. Davies, H. Geuter, Marguerite C. B. Grove, H. Y. Hain, F. M. Hall, H. Hughes, C. V. Kaula, J. G. Kendall, M. M. Lidgate, J. A. Litchfield, M. J. Lower, I. F. G. W. Marson, Winifred M. Mitchell, E. H. Mucklow, T. Mucklow, K. O. M. B. O'Meara, E. A. O'Neill, N. L. Owen, J. A. P. Pearce, P. G. H. T. Pollitt, IG. W. Poole, R. D. Poole, R. J. P. Push, E. T. Radford, R. G. W. Reeves, R. L. S. Richard, J. E. F. Riley, Audrey F. Roberts, B. S. Rose, R. W. Spencer, L. S. Stephens, E. J. Wadge.

The following scholarships, medals, and prizes have been awarded:

Queen's Scholarship (third year), L. W. Robinson; (fourth year) J. M. D. Roberts. *Ingleby Scholarship*, J. M. Mynors. *Foxwell Memorial Medal*, Margaret D. Thompson. *Gamp Memorial Medal*, Margaret L. Hampton. *Priesley Smith Prize in Ophthalmology*, Butterworth Prize, and *Queen's Scholarship* (final year), Theresa Lazar. *Queen's Scholarship* (fifth year), J. R. G. Bastable. *Leith-Newman Prizes in Pathology* (fourth year), Medical, R. F. Martin; Dental, E. A. Marsland. *Thompson Prize in Anatomy* (third year), L. W. Robinson. *Russell Memorial Prize*, F. G. W. Marson. *Hindie Prize in Anatomy*, M. G. Fitzgerald. *Barrist Nelson Memorial Gold Medal*, O. P. Gray.

1 Distinction in Medicine. 2 Distinction in Surgery.

UNIVERSITY OF DUBLIN

The following medical degrees were conferred on June 28 in the School of Physic, Trinity College, Dublin:

MD—F. S. Stewart.
M.B., B.Ch., B.A.O.—M. L. Ab-zhamson, S. Barnes, R. V. Barter, F. J. Burns, D. D. Crilly, J. J. Cussen, H. E. Devlin, L. Doyle, B. V. Earle, E. Fenelon, Mary Fitzmaurice, D. A. Good, W. E. R. Hackett, H. R. Hanna, Millicent R. Hopkins, W. H. Houston, A. R. B. Jackson, W. R. Keane, R. D. Lewis, D. D. McGrath, M. S. Millard, J. R. Moore, Betty R. O'Grady, E. G. Redman, P. R. Rees, H. H. Robinson, L. M. Roe, Margaret E. Rutherford, S. N. Rutherford, W. H. Rutherford, J. B. Ryder, Betty D. Scott, J. M. Stewart, V. O. Stewart, C. W. Sweetnam, A. B. Walsh, Mary L. Grove-White (formerly Wilson), W. T. C. Wilson.

UNIVERSITY OF LEEDS

The following have been successful at recent examinations:

M.D.—S. Wray.

FINAL M.B., CH.B. (Part I):—Rhoda M. Allison, Betty S. Astle, Joan L. Awmack, J. G. Benstead, 2G. L. Bickler, E. G. Brewin, J. L. Broadbent, 2A. K. Daniels, 1J. Davies, P. B. Dewes, O. P. Edmonds, G. R. Fryers, R. L. Gibson, Pauline H. Goss, Gertrude Harris, M. H. M. Harrison, J. R. Heseltine, Mary A. Hewett, J. D. Holdsworth, Dorothy D. Jones, L. Langton, F. A. Lodge, F. D. Lumb, 2F. McKennell, D. H. McMillan, Marjorie S. Oxley, J. G. Pearson, R. E. Riley, Joan M. Robinson, L. B. Robinson, 2R. J. Scothorne, H. Shooman, 12F. G. Smiddy, J. G. Smirk, Stella A. Speight, G. M. Thornton, E. J. S. Townsend, L. E. Wear, 2R. W. Wilkinson, 2Elizabeth Wilman, L. E. Wood, 2A. S. Woodcock, Ellen L. M. Wreford, H. J. Wright, A. D. Zermansky, D. Zimmerman, *Therapeutics*: Betty S. Astle, Joan L. Awmack, 3G. L. Bickler, J. L. Broadbent, K. J. Burnett, P. S. R. Burrell, A. K. Daniels, 3J. Davies, P. B. Dewes, R. L. Gibson, Pauline H. Goss, D. G. Hardy, Elizabeth M. Hargreaves, 3M. H. M. Harrison, Edith V. Heritage, J. R. Heseltine, Mary A. Hewett, J. D. Holdsworth, Dorothy D. Jones, Catherine M. Lamplugh, 3L. Langton, F. A. Lodge, J. McKennell, D. H. McMillan, J. G. Pearson, R. E. Riley, Joan M. Robinson, L. B. Robinson, R. J. Scothorne, H. Shooman, R. Sloman, F. G. Smiddy, Stella A. Speight, G. M. Thornton, L. E. Wear, R. W. Wilkinson, Elizabeth Wilman, L. E. Wood, A. S. Woodcock, Ellen L. M. Wreford, 3H. J. Wright, A. D. Zermansky, D. Zimmerman.

¹ Distinction in Public Health. ² Distinction in Forensic Medicine.

³ Distinction in Therapeutics.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—G. J. C. Brittain, P. Jones.

M.B., CH.B.—12J. V. Shephard, *Part III*: P. M. Edis, K. B. N. Freeman, N. J. Gourdie, Ethel J. Higgit, Constance G. Lee, Margaret J. Lezama, J. K. Meiring, Margaret Slater, A. Stone, Barbara K. Thompson, R. S. Williams, *Passed in Separate Subjects*: E. H. Ansell and A. Griffith (Medicine, Obstetrics, and Gynaecology), D. A. Harbord (Medicine and Surgery), *Part II*: H. B. Andrews, A. D. Charnley, E. Cooper, 3K. R. Dumbell, S. Gillis, J. T. W. Jones, S. Lipton, J. B. Roberts, *Passed in Separate Subject*: M. M. I. el Haddad (Public Health).

¹ Second-class honours. ² Distinction in Surgery. ³ Distinction in Public Health.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

M.D.—H. W. Clegg, E. L. Jones, 1E. L. Patterson, 2F. Stratton, Elizabeth C. S. Williams, R. V. Wright.

FINAL M.B., CH.B.—346R. W. Burslem, 3J. H. Diggle, 3Constance M. Duddle, 345John Hewett, 3P. Jewsbury, 344L. A. Liversedge, 34S. Olecsky, 3A. E. Thomas, F. Batley, D. G. Berry, Doreen M. M. Dutton, J. D. Heppleston, R. Heirons, 3Marjorie E. Jepson, F. Latham, Margaret M. Lawton, J. Leary, Marian B. T. McIntosh, Joan A. Meitani, B. Nicholson, T. A. Nowell, Nancy B. Penney, Leslie Rose, B. Samuels, P. W. E. Sheldon, J. A. Shrigley, H. Tabbusch, 3G. S. Tupman, W. V. Wadsworth, G. H. Watson, B. Wilkins, *Part I (Forensic Medicine and Hygiene and Preventive Medicine)*: Ruth A. Ainsworth, Constance Atkinson, George Bennett, J. L. Braithwaite, Merton Brooks, N. J. Caldwell, Ethel F. Caplan, Dorothy B. Charlton, C. L. Dubberley, Mary E. Eagles, S. S. Epstein, G. C. Fletcher, J. H. H. Gibson, Doreen H. Hayes, F. Howarth, P. Jewsbury, Margaret Laycock, L. A. Liversedge, Kathleen V. Lodge, K. Lowe, B. Marsden, Kathleen P. E. Mumford, Sylvia N. Nabarro, J. A. Noble, Joan E. Nuttall, M. H. Oelbaum, S. Olecsky, A. O. Osbaldeston, N. J. Roussak, E. P. Samuel, M. G. Saunders, Cecilia M. Smellie, J. P. Smith, Margaret E. Tate, Margaret M. Tutton, Marie R. West, Alice R. E. Widdows, J. D. Willis, Eric Wood, J. Wiseman.

¹ Gold medal. ² With commendation. ³ Awarded second-class honours. ⁴ Distinction in medicine. ⁵ Distinction in surgery. ⁶ Distinction in obstetrics.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

On July 6 three Fellows were elected into the Council to fill the vacancies caused by the retirement in rotation of Sir Robert Kelly, Mr. C. Max Page, and Major-Gen. W. H. Ogilvie. The following Fellows were elected:

William Henneage Ogilvie (Guy's)	572
Charles Max Page, C.B., D.S.O. (St. Thomas's)	490
Geoffrey Langdon Keynes (St. Bartholomew's)	341

The following were the other candidates:

Robert John McNeill Love (Royal Northern Hospital)	284
Percival John Moir, M.C. (General Infirmary, Leeds)	257
Victor Ewings Negus (King's College Hospital)	216
Robert Milnes Walker (Royal Hospital, Wolverhampton)	209
Arthur Dickson Wright (St. Mary's)	183
Herbert Henry Sampson, O.B.E., M.C. (Queen Elizabeth Hospital, Birmingham)	180
Rodney Honor Mainport (Royal Waterloo Hospital)	167
Charles Alexander Wells (Royal Liverpool United (Royal Southern Hospital))	166
Stanford Cade (Westminster)	147
Charles Walter Gordon Bryan, M.C. (St. Mary's)	79

In all 1,238 voted; in addition 3 votes were found to be invalid. Major-Gen. W. H. Ogilvie, Mr. C. Max Page, and Air Vice-Marshal G. L. Keynes are all elected for the full period of eight years.

An appeal for funds to provide a General Orde Charles Wingate Memorial Ward in the Princess Tsahai Memorial Hospital at Addis Ababa was launched at a meeting of friends of Ethiopia held in London recently. Donations may be sent to the hon. treasurer, Lord Horder, c/o H. Reynolds and Co., 1, Bloomsbury Court, High Holborn, W.C.1.

Medical Notes in Parliam

Feeding Scottish School-children

The House of Commons discussed the Scottish education Committee of Supply on June 4. Mr. JOHNES that there was an increase in the general aid grant at to £436,000. Of this, £398,000 would go to the e authorities and the balance to technical colleges and institutes generally. The increase of £398,000 to the authorities included a grant of £184,000 for milk in schools. The school-feeding grants had risen £471,000 to £655,000. This campaign for feeding in which was launched in the autumn of 1941, had been with increasing vigour. The number of children receiving at schools had increased from 50,000 in December to 175,000 in February, 1944, and during the past year numbers receiving dinner had increased by 50,000 and receiving lunches by almost 2,000. The percentage of meals at school was now over 25, an increase of 6% figure for 1943 and of 14% on that for 1942. The number of pupils receiving milk at school, as apart from meals increased by 14,000 during the past twelve months and now almost 69% of the entire school population of Scotland.

While school medical examinations had been restricted most parts of the country, what evidence there was remained continuing examinations went to show that the of the school-child was steadily improving, and in Glasgow particular the height and weight of the school-child brought entry to the registers and at the school-leaving dates materially improving over the figures for the last pre-war

Diagnosis of Smallpox at Mount Vernon Hospital

On July 4 Mr. VIANI asked the Minister of Health, in connexion with the announcements of his Department in the and on the radio in regard to the outbreak of smallpox at Mount Vernon Hospital, why no mention was made of the fact that the disease was introduced into the hospital by a returned soldier from the Middle East who was wrongly diagnosed as suffering from measles and chicken-pox, why the patient was not isolated, how this wrong diagnosis arose, and what was proposed to take to minimize the risk of similar mistakes in the future. Mr. WILLINK said that a statement to the effect that in the first part of the question was issued by his Department and was published in the medical press and in at least one lay newspaper. He was informed that the patient was first for measles and chicken-pox, and later, as soon as smallpox was diagnosed, in a smallpox hospital. The signs and symptoms observed by competent medical officers did not lead to the diagnosis of smallpox. This diagnosis was made retrospectively in the light of subsequent events. Diagnosis was made by the medical officer in attendance, but, since many medical officers had had no opportunity of familiarizing themselves with smallpox, he had enrolled in each region a panel of experienced to assist in diagnosis.

Medical Services of Ministry of Pensions

Introducing, on July 7, the Estimates for the Ministry of Pensions, Sir WALTER WOMERSLEY said his medical staff continued to set themselves a high standard of professional and administrative efficiency. In recent weeks Mr. Paling had visited a number of Ministry hospitals. Everywhere he found complete efficiency and readiness to meet the demands which must come as the war progressed. In spite of the man-power difficulties medical and hospital staffs would be found ready to meet all the demands upon them. One of the Ministry's hospitals had been put to a severe test, as it had been called upon to assist the Service Departments by acting as a clearing station for casualties brought back to this country from the time of the landing in Normandy. Many hundreds of men had passed through it, leaving as soon as they were fit for removal to another hospital for prolonged treatment. The arrangements had been completely satisfactory to the Service Departments. Another hospital had been adapted as a hospital for battle casualties coming from a clearing station. There, also, all requirements were fully met. Up to April 1944, officials of the Ministry of Labour interviewed 150 disabled persons in hospital so that the question of employment could be considered before discharge. Care was taken during hospital treatment to rehabilitate the disabled man to make him as fully able to work as possible. The result had been that 35,000 of those interviewed were able to take up work which they knew to be available for them, and 88,000 who for immediate employment were at once placed in jobs.

he remainder 11,000 were found to require training which would fit them for full employment. The number of cases in which the question of employment presented great difficulty was 2,231.

Limitation of Doctors' Lists

SIR LEONARD LYLE inquired on July 6 whether, in case of any shortage of doctors to meet the requirements of a State health insurance scheme applicable to everybody, it was proposed to remove any limit on the number of panel patients registered with a medical man, or to use compulsion to bring in a sufficient quota of doctors. Mr WILLINK replied that it was not proposed to compel any doctor to take any part in the new service. The appropriate limits to the number of patients whose care a doctor should be able to undertake within the service would need to be considered fully with the medical profession when the proper time came.

Criminal Lunatics—On July 4 Mr HERBERT MORRISON, replying to Dr Salter, said that the numbers of persons certified insane under Section 2 of the Criminal Lunatics Act, 1884, in prisons and Borstal institutions and removed to mental hospitals, including Broadmoor Asylum during each of the last five years were 1939, 88, 1940, 83, 1941, 64, 1942, 86, and 1943, 69.

Deaths from Cancer—Mr WILLINK informed Mr Leach on July 4 that the numbers of deaths from cancer registered in England and Wales during the years 1939 to 1943 were 1939 67,154, 1940, 68,922, 1941, 69,227, 1942, 70,419, and 1943, 72,158 (provisional).

Institutional Accommodation for Tuberculosis—On July 4 Captain McEWEN informed Sir Waldron Smithers that at March 31, 1944, the latest date for which figures were available, the number of tuberculous cases in England and Wales which had been awaiting institutional treatment provided by tuberculosis authorities for a period of more than ten days was 3,960. The figure for Kent at the same date was 236 cases.

Admission to Sanatoria—SIR WALDRON SMITHERS inquired on July 6 whether it was the policy to admit advanced cases of tuberculosis to sanatoria or to select those who were more likely to recover or to admit patients in accordance with the date of recommendation. Mr WILLINK answered that the admission of tuberculous persons to hospitals or sanatoria was the responsibility of the tuberculosis authority, acting on the advice of its appropriate medical officer. There were differences in practice, but it was general to select patients for admission on clinical grounds and not in accordance with the date of recommendation. In general, selection for admission to particular institutions was made on the merits of the individual cases.

Notes in Brief

The Minister of Health stated in the House of Commons recently that the number of new cases of tuberculosis in England and Wales notified in 1943 showed an increase of 18.4% over 1939, but the number of deaths which was considered the truest guide to the incidence of the disease, showed an increase of only 0.1% over the same period.

Medical News

The twenty-third annual general meeting of the Medical Society for the Study of Venereal Diseases will be held on Saturday, July 22, at 2.30 p.m. at 11, Chandos Street, Cavendish Square W.1. After the transaction of business Dr J. A. Scott will give an address on venereal diseases in the Soviet Union.

It has been decided to postpone the conference on "The Nutritional Role of the Micro-flora in the Alimentary Tract," which the English Group of the Nutrition Society was to have held on Saturday, July 22, at the London School of Hygiene and Tropical Medicine. An announcement of the revised arrangements will be made later.

The Joint Committee for Soviet Aid, honouring the memory of the Soviet General Vatuln, who died in April of this year, has launched a £20,000 fund for medical supplies and comforts for the Red Army and the liberated peoples of the Soviet Union. Among the first donations to this fund was one from General Eisenhower, who sent the following message: "The death of General Vatuln at Kiev is an irreparable loss, not only to the Soviet Union but also to the United Nations. His name will always live in the annals of great military leaders. I can imagine no finer memorial to a soldier than the provision of medical supplies and comforts to the fighting men of his country and the peoples they have liberated. I should like personally to contribute to your campaign." Cheques for the fund should be made payable to the hon. treasurer, Sir Peter Chalmers Mitchell, Joint Committee for Soviet Aid, 171, St. Stephen's House, Westminster, London, S.W.1.

The Minister of Supply has appointed Prof. H. Raistrick, F.R.S., as honorary scientific adviser on penicillin production. Prof. Raistrick is a member of the General Penicillin Committee and holds the chair of biochemistry at the London School of Hygiene and Tropical Medicine (University of London).

Through His Majesty's Ambassador in Chungking, the Director of the Chinese National Central Library generously offers to provide British scholars with Chinese material for specialist researches, and to arrange for its translation into English if desired. The Library will also forward lists of books available to interested institutions in this country. The British Council, in gratefully acknowledging this offer, has undertaken to act as intermediary on the British side, and will answer inquiries about the scheme, which should be addressed to the Director, Books Department, British Council, 3, Hanover Street, London, W.1.

The Ministry of Health has informed local authorities that information obtained through Regulation 33B may be disclosed to medical authorities of H.M. Forces or those of the United States or other Allied or associated Forces so far as this is necessary to secure examination and treatment of persons alleged to be sources of infection. Local authorities should send particulars of any member of these Services who is named on a Form I received by the medical officer of health to the medical authorities of the Service concerned.

There are still more than 3,000,000 children in England and Wales unprotected against diphtheria, states a Ministry of Health appeal to the country's 25,000 chemists and druggists in a special bulletin sent to the *Pharmaceutical Journal* urging them to recommend immunization. By the end of last year the number immunized in England and Wales under local authority arrangements was 4,880,000, and it is estimated that the total then stood at 46% of all children under 15. About two thirds of those between the ages of 5 and 15 but only one third of the under fives, who are more susceptible to the disease, were then protected. Twenty nine out of every thirty children who died from diphtheria were not immunized. The number protected last year was 1,051,660 against 1,399,751 the year before and, it is pointed out, if this reduction continues, we shall hardly be keeping pace with the birth rate.

On April 15 the Save the Children Fund (20 Gordon Square, W.C.1) attained its twenty-fifth anniversary. The fund is the only international organization for child welfare in the world. Founded after the last war as a measure of relief for child victims, it has expanded to a world-wide organization for child welfare and has extended its influence to 40 different countries. In collaboration with the Council of British Societies for Relief Abroad, the officially recognized body for the co-ordination of voluntary relief effort, it is sending highly trained units to a foreign base for service in whatever lands they may be asked to work in. They will concentrate on the care of children and in co-operation with the national organizations of the Save the Children International Union where they exist, will be prepared to assist in the reorganization of child welfare work.

The Minister of Health has reappointed the Advisory Committee on the Welfare of the Blind for a further period of three years. The committee is constituted so as to afford representation to the local authorities concerned with the working of the Blind Persons Acts, and to voluntary associations for the blind, as well as to organized blind workers.

The Association of Scientific Workers has issued from 73, High Holborn, W.C.1, a memorandum on "A Post war Policy for Science," adopted by its council as a statement for discussion which it hopes to expand later in further publications. The reference to medical research runs as follows: "The present organization, including philanthropic foundations, universities, hospitals, manufacturing firms etc., will obviously continue after the war. This varied organization is not necessarily bad, but may leave large and notable gaps. The Medical Research Council should enlarge its activities and undertake a more effective co-ordination of those bodies. It should extend its use of teams to tackle special problems and should support more permanent full time research workers. Research institutes should maintain closer contact with hospitals. There should be considerable central and local expansion of industrial medicine. This might include the establishment of a central institute for industrial pathology and similar subjects. Application of existing knowledge to the benefit of the community is partly a problem of social organization. For this reason the A.S.W. has for some time supported a State Medical Service. As a problem of internal organization, better clerical assistance, uniform medical records, better assistance in diagnosis and access to data would reveal new information about morbidity and expose new problems. The medical sciences will also face the problem of a shortage of personnel. This will be relieved to some extent by workers demobilized from the Services but further facilities for training will have to be established."

The December, 1943, issue of the *Bulletin of the History of Medicine* is devoted to Vesalius.

The issue of the *Schweizerische Medizinische Wochenschrift* for April 15 is dedicated to Dr. Ernst Oppikofer, professor of oto-rhino-laryngology at Basle, on the occasion of his 70th birthday.

The late Dr. C. E. Douglas of St. Andrews, among other charitable bequests, left £1,000 to the British Medical Association's Charities Fund.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week the incidence of whooping-cough, scarlet fever, and measles dropped by 204, 93, and 85 respectively. There was a slight rise (31 cases) in the notifications of diphtheria; during the past five weeks the average number of cases of this disease has reached the low level of 478. The local trends of scarlet fever underwent little change during the week. Although there were fewer notifications of whooping-cough, the largest local variations were rises in Cheshire and Warwickshire—which reported respectively 47 and 40 more cases than last week—and a decrease of 40 cases in Kent. London and Lancashire each had 60 fewer cases of measles than last week, and Middlesex 40; the greatest rises in this disease were 57 in Southampton and 47 in Kent.

Dysentery notifications went up by 10 during the week. The chief outbreak was in Glamorganshire 59 (Penarth U.D. 46, Cardiff C.B. 11). The other large returns were from Lancashire 31, Sussex 16, Yorks West Riding 11, Warwickshire 10, London 10.

In Scotland notifications of measles were 147 fewer than last week, whooping-cough 44, and scarlet fever 27. Glasgow reported 37 and Edinburgh 13 of the total of 88 cases of dysentery—a total 25 higher than last week. Of the 22 cases of typhoid fever 19 were notified in Glasgow.

In Eire the notifications of diphtheria fell from 82 to 55. The largest return for measles was Clare, Ennis U.D. 42. One case of typhus fever was reported from Galway, Oughterard R.D., this being the fifth case recorded in Eire in the last six weeks.

In Northern Ireland all the 45 notifications of measles and 26 of the 56 cases of scarlet fever were recorded in Belfast C.B.

Week Ending July 1

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,437, whooping-cough 2,382, diphtheria 432, measles 2,503, acute pneumonia 558, cerebrospinal fever 44, dysentery 135, paratyphoid 2, typhoid 10.

Tuberculosis during 1914-18 and 1939-43

In 1914 and again in 1939 the outbreak of war was the direct cause of a rise in tuberculosis mortality. The deaths rose during 1939-41 and then fell; in 1914-18 the mortality continued to increase throughout the war. The deaths for the two periods in England and Wales are:

Year	Pulmonary	Non-pulmonary	Year	Pulmonary	Non-pulmonary
1914	37,838	12,460	1939	21,542	4,081
1915	40,803	13,492	1940	23,660	4,434
1916	40,769	13,089	1941	23,633	5,037
17	42,335	13,599	1942	20,989	4,560
18	45,338	12,735	1943	21,340	4,310

The rise in mortality during 1939-41 affected mainly children, old men, and young women. The relative increase for all ages was approximately the same for both sexes. During 1914-18 the increased mortality was concentrated on ages 5-45, with a peak at ages 15-20. The females suffered a higher relative increase than did the males. The percentage increases in death rates from 1914 to 1918 during young adult ages from all forms of tuberculosis were 42, 20, 20 for males aged 15-19, 20-24, 25-34, and 48, 39, 30 for females.

Table Correction

In the epidemiological table printed at page 32 of the issue of July 1 the notifications for influenzal pneumonia and for primary pneumonia were reversed in the four columns for 1944. Thus the notifications for England and Wales for influenzal pneumonia should have been 738, for London 61, for Scotland 200, and for Eire 26; for primary pneumonia there should have been no notifications for England and Wales or for London (these being included under influenzal pneumonia as usual), 5 for Scotland, 2 for Eire, and 8 for Northern Ireland.

A report of the conference on the part which social workers can play in the Beveridge plan for social security, which was held in London last year by the British Federation of Social Workers, has now been published and can be had from the offices of the Federation, 5, Victoria Street, S.W.1. It contains the text of the four addresses (also some discussion), including that by Mr. Somerville Hastings on the place of the social worker in a unified health service, and that by Prof. Sargent Florence on the importance of trained personnel.

INFECTIOUS DISEASES AND VITAL STAT

We print below a summary of Infectious Diseases and Statistics in the British Isles during the week ended 1

Figures of Principal Notifiable Diseases for the week and those for corresponding week last year, for: (a) England and Wales (London included) (administrative county). (c) Scotland. (d) Eire. (e) Northern

Figures of Births and Deaths, and of Deaths recorded under each infection are for: (a) The 126 great towns in England and Wales (including London (administrative county)). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not not no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Altiolox Western*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

those desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Western*, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: *Meduocera Western*, London.

M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Diagnosis of Acute Abdominal Disease

Q.—Pethidine is coming into prominence as a pain-relieving drug, in many cases is replacing morphine. Can pethidine be given in cases of acute abdominal pain in which the diagnosis is not clear and the patient needs watching, without the fear of physical signs being removed, as in the case of morphine?

A.—The question at issue is whether pethidine will relieve the pain of colic but not that of peritonitis. It is generally accepted at this drug relieves spasm, though it cannot be relied upon contently to do so; but its effect in peritonitis is variable—it may act as morphine does, but again it is unreliable. It would therefore appear to be a most unsuitable drug to use in an undiagnosed case. Furthermore, there are reliable antispasmodics such as the nitrites, or calcium salts given intravenously, which are effective only in relieving colic. It must be pointed out, however, that experiment with drugs is not to be favoured as a method of establishing the nature of acute abdominal disease.

Treatment of Infantile Uterus

Q.—A patient aged 18 has complained of a primary type of dysmenorrhoea for the past three years. On examination under anaesthetic she has a uterus one inch long, anteverted and anteverted. She has no other signs of any endocrine upset. Would she benefit from any hormone treatment? If so, would you give details of the preparation, dosage, and length of time it should be continued?

A.—This is clearly a case of infantile uterus and it is quite likely that it will respond to treatment with oestrogens. The synthetic estrogen, stilboestrol, is easily obtainable and should be tried first. A dosage of 3 mg. a day is recommended, and this should be given only in the first half of the cycle—i.e., for a fortnight after the onset of the menstrual period. The patient should be warned that it may be three months or more before she experiences any benefit from the treatment. Stilboestrol causes nausea and vomiting in about 20% of non-pregnant patients. Should this occur, another synthetic product, hexoestrol, should be tried in the same doses. Hexoestrol causes vomiting in only about 5% of non-pregnant patients. Should neither stilboestrol nor hexoestrol be tolerated, oestradiol benzoate in doses of 50,000 i.u. should be given by injection twice weekly in the first half of the cycle. Treatment should be continued for six months and the patient then re-examined to see if there has been any increase in the size of the uterus. If the uterus is enlarged and the symptoms are relieved, no further treatment will be required. Hormonal treatment in these cases should be combined with general hygienic measures, such as regular exercise in the open air, attention to constipation, and so on. Cases that are refractory to hormone therapy present a difficult problem, but if hormone treatment fails and the dysmenorrhoea is severe enough to incapacitate the patient, a presacral neurectomy might be considered.

Enlarged Tonsils

Q.—In view of the diversity of opinion, can you recommend the best line of treatment for enlarged tonsils in a child aged 2, no mouth breathing at present, otherwise healthy but liable to recurrent colds?

A.—There is scarcely enough information to answer this. Are the glands in the neck enlarged? Have there been any attacks of tonsillitis? Does the enlargement date from a recent acute specific fever? It is disappointing to remove tonsils for recurrent "colds," would be worth while deciding whether these "colds" are caught from some other member of the household or if they develop

spontaneously. In the latter case what is the state of the antra? It would be worth while using some nasal drops such as ung. hyd. nit. dil. 30 gr., arachis oil to 1 oz. If the tonsils look unhealthy and the child is at all co-operative, painting them with Mändl's paint might be considered.

Deafness in a Young Man

Q.—A man aged 33 has otosclerosis which first manifested itself at the age of 16, when he suffered much from nasopharyngeal catarrh; but there was never any Eustachian obstruction. Bone conduction is quite good. The hearing slowly and steadily deteriorated until a few years ago, since when there has been very little, if any, change. There is no tinnitus or any other complication, and the general health is good. His mother suffered in a lesser degree at the age of 27, but improvement followed after a few years without any treatment.

*A.—It is impossible to say without examining the patient whether he is suffering from a chronic adhesive process which has become established and stationary, or from otosclerosis, and even on examination it might be difficult to make a decided diagnosis. If the case is one of otosclerosis, the history both familial and personal being rather in favour of this, the deafness is likely in the long run to be progressive. No treatment locally is of any avail whatever, and these patients are subjected to incessant exploitation. A suitable hearing aid, if the degree of deafness demands it, is the best means of overcoming the disability. The operation of fenestration of the labyrinth was referred to on page 445 of the *Journal* of March 25, 1944; the purpose of this is to improve the hearing by making a permanent opening into one of the semicircular canals, the lateral canal being usually chosen. This, however, could not be recommended without a careful examination and evaluation of the deafness in the particular case, and the results are uncertain.*

Treatment of Lumbago

Q.—A patient has for many years suffered from attacks of lumbago. Recently these attacks have become more severe, and occasion great distress and incapacity. Treatment, including infiltration with local anaesthesia, has been unavailing. The muscles affected are those of the lumbo-sacral region. What is the modern conception of this disease, and how is it best treated?

A.—Further investigation of this case would appear to be required, including x-ray examination of the lumbar spine and sacro-iliac region—antero-posterior, lateral, and oblique. Some anatomical abnormality may be present predisposing to strain; this appears to be frequent in the presence of sacralization of the fifth lumbar vertebra, or the similar condition, "lumbization" of the first sacral segment. If there is any evidence that the attacks are apt to follow any physical effort, particularly bending, wearing a properly fitted belt might be helpful, but stress must be laid on such a belt being designed to give genuine support. Many of the belts worn by victims of lumbago are worse than useless. Capener, in a Hunterian Lecture in 1941, dealt with the anatomical basis of the strains liable to occur in this region. The acute attacks may be due to spasm of the quadratus lumborum and associated muscles.

If physical causes can be excluded, gout may be the cause, and an examination of the blood for the uric acid content may throw a light on the problem; anything over 4 mg. of uric acid per 100 c.cm. will be suggestive. If this should prove to be the case, cinchophen will be the appropriate remedy for the acute attacks in doses of half a gramme thrice a day for three days, followed by an interval of from five to seven days. Between the attacks an eliminant such as diuromil may be taken with advantage. When testing for the blood uric acid the sedimentation rate should also be determined. It may be slightly accelerated in gout, but any marked increase will indicate the probability of an infective origin, and search should be made for the probable focus, which may very possibly lie in the prostate though not necessarily being gonorrhoeal in nature. In any case rectal examination is desirable. As general lines of treatment, heat, massage, and manipulation will be indicated; and a course of treatment at a spa, which would probably mean the use of such methods together with measures to promote elimination, might be a profitable way of spending a holiday.

Treatment of Molluscum Contagiosum

Q.—A young woman has molluscum contagiosum on her face, confirmed microscopically. The treatment prescribed is the usual one of excision and cauterization. This I have done on several occasions. Fresh crops appear at intervals of about 10 days. Is there any other and more satisfactory way of treating this condition?

A.—In molluscum contagiosum pricking the lesions with a sharp scalpel, squeezing out the contents, and spotting with tincture of iodine is almost invariably successful. In view of the simplicity and certainty of local treatment, the use of sulphonamides, as recently recommended, seems hardly called for.

Possible Thyroid and Ovarian Deficiency

Q.—A married woman aged 36 (1-para) has felt the cold intensely for the last few years, has suffered from chilblains, and has noticed an increased growth of hair on the upper lip. During this time menstruation has been less profuse, her periods lasting only about three days. What endocrine treatment, if any, would be useful?

A.—The story suggests the onset of thyroid and ovarian deficiency, a not uncommon combination and one which might almost be expected in view of the common origin in the basophil cells of the pituitary factors controlling thyroid and ovarian function. Thyroid should be given by mouth, starting with a dose of 1 gr. every morning and gradually increasing until either the result is achieved or symptoms of intolerance occur. Oestrogenic treatment—e.g., hexoestrol by mouth, 5 mg. twice daily—should be given, but not continuously. It is better to instruct the patient to take the drug for a fortnight only, after the end of each menstrual period. The natural oestrogen tide is thus very roughly copied and the regularity of menstruation unaffected in most patients.

Prophylaxis in Allergic Child

Q.—I should be grateful for advice on the immunization against diphtheria of two children, now aged 7½ and 6 years, who in infancy showed intense allergy to all forms of milk, with severe anaphylactic reactions during attempts at desensitization. They also showed a tendency to develop sensitivity to other protein foods. During the past two years the only allergic symptoms have been three slight attacks of asthma in the older child (each associated with coryza), and a tendency to develop sensitivity to fish and eggs in the younger (with papular urticaria and oedema of the hard palate as symptoms). Neither child has been vaccinated. There is a family history of allergy in both parents.

A.—Many an immunologist would Schick-test the children and, if they were positive, would give a small dose—e.g., 0.1 c.cm. of A.P.T. (not T.A.F. or T.A.M.). If no local or general reaction occurred, he would probably give a second dose of 0.2 c.cm. a fortnight later, followed by a third dose of 0.2 c.cm. a fortnight later still. Such a procedure might work satisfactorily. For my part, I should be extremely circumspect with such highly allergic children. I should Schick-test. If any "pseudo"-reaction occurred—even pseudo and positive—I should be hesitant to go further (hoping that the reaction indicated a trace of potential immunity). Only under parental pressure and assumption of responsibility would I give prophylactic, choosing, of course, A.P.T. I should start with minute doses—e.g., 0.1 c.cm. of a 1:10 dilution. In the absence of any troublesome local or general reaction, I should next day give 0.1 c.cm. of undiluted A.P.T., followed by two further doses of 0.2 c.cm. at fortnightly intervals (see *Journal*, 1940, 1, 292; 1942, 1, 534; and *Lancet*, 1936, 2, 310).

INCOME TAX**Purchase of Practice: Loan from Insurance Company**

T. has bought a practice with the aid of an insurance company, repaying £500 a year—roughly £350 premium and £150 interest. Is he entitled to any deduction for these payments?

****** So far as the payments represent premiums for insurance on his life, T. is entitled to the statutory "life insurance relief," to be claimed by filling up the appropriate space on the income tax return form. So far as they are payments of interest no allowance is due, but presumably the income tax on that portion of the payments is deducted so that T. pays only a net amount and receives an allowance in that way.

"Pay as you Earn"

A. retired three years ago, but has in the last two years been serving on medical boards. The fees constitute his only earned income. Some other retired members of the board are not being dealt with under "pay as you earn." Why is this?

****** If the other members have no professional earnings other than these fees they would in the ordinary course have tax deducted under the "pay-as-you-earn" system, unless the various allowances to which they are entitled exceed the fees from the board. But until the system has been working for some time differences of practice are not unlikely to occur. It should be remembered that whether tax is deducted or not does not alter the amount ultimately to be paid.

A. R. last year "earned spasmodically, doing house jobs and locumtenent work"; this year he has an assistantship and pays tax under the "pay-as-you-earn" system. Must he pay last year's tax as well?

****** Yes. The professional work last year was carried on in a manner which brought the earnings within the field of assessment under Schedule D. If he had been an assistant last year assessable under Schedule E there would have been some relief due to him, but that relief does not apply to tax under Schedule D.

Information from Bank Account

E. L. has been asked by the inspector of taxes to let him the amount standing to his credit at the bank at April 5, 1944. He would prefer to quote only the difference between these figures and not the figures themselves.

****** We should advise our correspondent to quote the figures for in spite of the fact that they may disclose to some extent amount of "savings." A statement of total income, which required from everybody, shows particulars of property and investments, so that some inference as to the extent of "saving" usually possible to the inspector of taxes when dealing with accounts.

LETTERS, NOTES, ETC.**The D.P.M.: A Minimum Requirement**

"MAJOR R.A.M.C., SENIOR PSYCHIATRIST," writes: It is greatly to be welcomed that the standard of the diploma in psychological medicine has been raised. It is also a wholesome advance that this diploma will be made the minimum requirement for those wanting to practise as specialists in psychiatry, psychology, or mental deficiency. The present annual value of the diploma is £50—not an outstanding reward for passing a two-part examination requiring at least months' special training, apart from the extensive study and practice that alone can give the beginner his basic knowledge of "what is all about." But whether the purposes of the diploma are served by making the highest possible knowledge of neurology its condition seems very problematic. The practice savours of introduction of an intelligence test factor into the exam., for it is not only those who can raise time, interest, and gift for a subject in which they are not going to practise can ever hope to be given permission to exercise their talents or achievements as doctors of the mind. Thus a mental deficiency officer of a score years' standing will be declared unfit for his job, while the youngster who time and opportunity to swot hard in neurology will take his first wet diploma in his hand. At one time the policy was to encourage the G.P. to take up psychology. There used also to be provisions for separate examinations for psychological medicine for mental deficiency. To-day anyone entering hopefully for the latter course would wait in vain for an opportunity for declaration of his choice, and the busy G.P. is not given any better chances as the fresher. Nor are any allowances made for those serving H.M. Forces, who may not have had a chance in years to sit microscopical slides or formalin specimens kept in museums. The who took a D.P.M. course in the first year of the war must feel that their teachers have misled them completely about the standard requirements if they presented themselves four years later. I feel now that the brilliant young neurologist can easily pass both parts of the exam. without, for that matter, convincing us that he will really be a first-rate psychiatrist or psychologist. If the standard of the examination is a raised standard of efficiency of person engaged in psychological medicine or mental deficiency, the present policy must be considered a failure.

Grenz Rays

Dr. Z. A. LEITNER (London, W.1) writes: Your questioner (July 24, p. 862) might find further information about Grenz rays in the following recently published papers: *Brit. J. Radiol.*, 1938, 11, 59; *Proc. roy. Soc. Med.*, 1943, 36, 428; and *Brit. J. phys. Med.*, 1946, 114.

Offers of Hospitality for Doctors' Children

Dr. X., practising in Huddersfield, inquires whether a colleague in London would like to evacuate a child because of the danger from the flying bombs. The doctor in question, who has a daughter aged 9, kindly offers to accommodate a girl of about 10 years of age.

Dr. Y., of Teignmouth, Devon, who has a large empty bedroom with one double and one single bed, offers to accommodate accompanied children of a London colleague, on condition that the parents accompanying them will be prepared to look after their room and help generally in running the house. Only such payment as would cover expenses would be expected. Dr. Y. adds: "Later on if the doctor himself could snatch a few days we could probably find him in."

Any readers interested in either of these offers may communicate with the Secretary at B.M.A. House, Tavistock Square, London, W.C.1.

Visits of Indian Scientists: Correction

On page 577 of the *Journal* of April 22 there was a reference to the report of the Delhi Correspondent of the *Times* regarding the forthcoming visit of Indian scientists to England. Among the persons included in the delegation we mentioned "Col. H. L. Bhatia, Deputy Director of the Indian Medical Service." The correct name and designation of this officer are: Col. S. L. Bhatia, M.C., M.S., Deputy Director-General, Indian Medical Service, New Delhi.

LONDON SATURDAY JULY 22 1944

SOME PROBLEMS IN RIBOFLAVIN AND ALLIED DEFICIENCIES*

BY

HUGH S. STANNUS, M.D., Ph.D., F.R.C.P.

I have chosen as the subject of these lectures one which I think may be discussed with advantage just now when nutrition is a matter very much to the forefront in Britain, when the problem of malnutrition among the native inhabitants of our Colonies is still awaiting solution, and when plans for feeding the starving peoples of enemy-occupied countries are being considered. First, I shall discuss a syndrome recognized many years ago and then later further defined, and its relation to the condition to which the term "aribo flavinosis" was assigned by Sebrell and Butler (1938). I shall then suggest a tentative explanation of the pathogenesis of the signs and symptoms of riboflavin deficiency and of their peculiar localization, based on an anatomico-physiological consideration of the capillary vascular system. In this abridged form it will not be possible to do more than give an outline of my thesis, and much detail and full references will perforce be omitted.

Early Personal Observations

Just over 30 years ago—in 1912–13—I published an account of the first outbreak of pellagra to be recognized in Africa, apart from Egypt, when I was afforded the opportunity of proving for the first time that that disease had no intrinsic relationship with the consumption of maize, as the subjects, long-term prisoners in Nyasaland, had been maintained on rice. I drew attention to a group of symptoms which tended to precede the onset of the more classical signs of pellagra by many months or which, indeed, persisted without those signs appearing. This group of symptoms included soreness of the tongue and lips, with a very characteristic lesion at the corners of the mouth; associated with a similar condition about the nostrils, the palpebral fissures, the free border of the prepuce, the vulva and anus, together with a dermatosis of the scrotum, often also involving the skin of the adjacent part of the thigh.

More important still, it was found that the syndrome above described, in its less fully developed form limited usually to the affection of the corners of the mouth, lips, and tongue, was not uncommon among the general native population. Further inquiries elicited the fact that this affection occurred in other parts of East Africa, and two interesting points came to light—first, that the condition, associated with obscure nervous symptoms, was common among native children at a mission boarding-school in Zanzibar; and, secondly, that their symptoms cleared up when they returned to their villages for the long vacation.

I had noted among my prison cases various neurological symptoms, including deafness and diminution of vision with loss of pupillary sphincter tone, but did not, at that time, associate them with the syndrome under discussion. I believed that pellagra and this syndrome were the result of dietetic deficiency; but these were early days, just about the time when Funk was engaged in preparing Factor B and when the word "vitamine" was introduced.

The importance of these early observations lay in the fact that this was the first time that attention had been drawn to the occurrence of this group of symptoms, due to a dietetic deficiency—dissociated from pellagra. Each, as a symptom occurring in pellagra, was in no way new, as a perusal of the writings of the older pellagrologists from Casal (1730) downwards will show.

In 1911 I drew attention to a long-forgotten description by Strachan (1888) of a condition among natives in Jamaica, believed by him to be "malarial multiple peripheral neuritis," in which mention is made of practically all the same symptoms; and in 1930 I pointed out the resemblances between a condition described by Scott (1918) as "central neuritis" of toxic origin, among Jamaican labourers, and the syndrome under discussion.

Collected Observations

Later, in 1936, I collected together and reviewed a number of interesting observations which had been published in the meantime upon conditions which I considered were akin to the original syndrome. I used the expression "pellagra-like conditions" to focus attention upon malnutrition as the basis of causation. The close connexion was obvious then, as it is now, when we recognize the close relationship between nicotinic acid and riboflavin in the vitamin B₂ complex and the relation of each to pellagra.

Among these observations were a number which had reference to an affection only of the tongue, lips, and the angles of the mouth. These I shall not consider further. (Blacklock, Sierra Leone, 1925; Jamin, Tunisia, 1925; Nogue, Dakar, 1925; Mathis and Guillet, Dakar, 1925; Gayot, Dakar, 1920; Brocq and Paultrier, Fréjus, 1928, 1939; also Barlovatz, Congo, 1940.) It will not be possible either to discuss here the very interesting condition occurring among infants in East and West Africa and elsewhere which I have referred to as infantile pellagra, but in which riboflavin deficiency probably plays a major part.

The remainder, to which have been added a few published more recently, are shown in the Table (under D) for the sake of brevity. They constitute, I believe, a series showing manifestations of the same syndrome in more or less complete form. The disparities may be explained in part, I think, by the fact that in some cases the descriptions are not very full and are obviously incomplete, the period of observation is short, and opportunities for exhaustive examination are lacking. In other cases want of exact parallelism may be due to variations in the comparative intensity and duration of the causative process.

Fitzgerald Moore's observations are of particular importance, for to him belongs the credit of recognizing that the disease which was rendering thousands of natives nearly blind was due to a dietetic deficiency and was amenable to treatment with marmite. His first paper was published in 1930. From this and those published subsequently, and a number of personal communications, a fairly complete picture of the affection can be drawn—one that reproduces the original syndrome described, but unassociated in any way with the dermal and other classical symptoms of pellagra. The second communication of importance was that by Landor and Pallister in 1935. They

described a condition which practically duplicated that recorded by Fitzgerald Moore. They showed that recovery took place when treatment with autoclaved yeast or autoclaved marmite was given. Fitzgerald Moore's cases also responded to the same preparations. This result excluded vitamin B₁ as a factor in causation. Fitzgerald Moore was also able to show that vitamin A played no part, and later that nicotinic acid had no curative effect. That author was more particularly interested in the ophthalmological condition. In early cases complaining of dimness of vision, with, or with a history of, sore lips and sore tongue, no changes were found in the fundi. Later, pallor of the temporal halves of the disks was noted, in some optic atrophy, in others signs of optic neuritis. Central scotoma and some retraction of fields were demonstrated in a few cases. Loss of pupillary tone and photophobia were also noted. The nervous symptoms, apart from loss of visual and auditory acuity, consisted of some mental dullness, a sense of muscular weakness, ataxia, and paraesthesiae.

It is of interest to recall the fact that Goldberger and Tanner in 1915 and 1925 produced experimentally some of the symptoms of this syndrome and referred to them as "pellagra sine pellagra," as I had previously done, but they were apparently unaware of my observations. It is also of interest to remark the similarity of the signs and symptoms in animals—the rat and the dog—but space will not allow of their discussion here.

At the end of 1938 Sebrell and Butler published their preliminary note on "Riboflavin Deficiency in Man." Nicotinic acid and riboflavin had then been isolated from vitamin B₂-complex. The results of experiments on animals fed riboflavin-free diets and certain observations on nicotinic-acid-treated pellagrins led these observers to repeat Goldberger and Tanner's feeding experiments. Of 18 women so treated 10 developed in from 94 to 130 days lesions on the lips, at the angles of the mouth, in the vestibule of the nose, etc., comparable to those described by Goldberger and Tanner and those described by myself—a fact which the authors immediately recognized. These lesions cleared up under treatment with riboflavin.

Thus then was given the first demonstration of the relationship of some part of the original syndrome with riboflavin deficiency. These authors suggested that "the term ariboflavinosis be added to the nomenclature of the vitamin-deficiency diseases, as a designation for the clinical condition due to riboflavin deficiency." Since there is reason to believe that death ensues long before the advent of a-riboflavinosis, I prefer to use the term "hypo-riboflavinosis."

During the following three or four years other symptoms were added to the original "ariboflavinosis" syndrome by

observers in the United States, chief among them being Sydenstricker and his colleagues, the diagnostic criterion in a cases being a response to riboflavin therapy.

Again, though there are differences between the symptom and signs enumerated under ariboflavinosis and those included in the older syndrome, I think that they may be looked upon as differences in degree and that they may be explained along the lines above mentioned (see Table, F). Further, many of the groups of symptoms, combined into a series of overlapping syndromes due to malnutrition during the Civil War of 1936-9—described by Spanish observers although, as they stated, unfamiliar to them—reproduced those which I have shown were recognized years before (see Table, E). The symptoms will be dealt with in greater detail when I come to speak of their pathogenesis.

Although there are reasons, on epidemiological grounds, for believing that all the signs and symptoms I have grouped together should be considered as parts of a single clinical entity due to riboflavin deficiency, we cannot at the present time exclude the possibility that some other factor—perhaps some other member of the vitamin B₂ complex—plays a part. For the sake of brevity, however, in what follows I shall speak only of hypo-riboflavinosis.

The Action of Riboflavin

Riboflavin is generally held to be present in the cells of every tissue of the body. Like other members of the B group of vitamins—not in themselves enzymes or catalysts, but components of chemical combinations, known as coenzymes, which in conjunction with specific proteins, the apo-enzymes, form a number of systems essential for the breakdown of carbohydrates with the release of energy little by little—riboflavin, combined in the form of a flavoprotein, acts by alternately accepting and releasing two atoms of hydrogen, and thus participates in a number of reactions in connexion with carbohydrate metabolism, and among them that which forms the link between the anaerobic dehydrogenase system and the aerobic cytochrome : cytochrome-oxidase : oxygen system. Oxidation may be defined as the change of an atom or ion from a state of lower valence to a state of higher valence. Reduction is the reverse. Oxidation in the sense of biological oxidation of carbohydrate may be effected by the addition of oxygen, by the removal of hydrogen, or by the withdrawal of one or more electrons (or negative charges), without the equivalent transfer of oxygen or hydrogen.

All the stages of the complicated series of processes involved in the release of energy from the carbohydrate molecule are not well understood, but the following schematic set of equations will serve to demonstrate the principle involved and

indicate the close association of riboflavin with the utilization of carbohydrate and oxygen

Since riboflavin is associated with intracellular catalytic processes any deficiency may be expected to give rise to a metabolic disturbance in every cell of the body

In the past it has been customary when thinking of any tissue merely to assume a cellular deficiency of riboflavin without considering how that deficiency comes about. I propose, therefore to discuss some part of this problem

The Role of the Capillary System

Perhaps we do not always realize that the vascular system has been developed for a single purpose—that of carrying to the immediate environment of each individual cell all the essentials to satisfy its needs, thus creating an environment comparable to that of a unicellular organism. The actual living parts of complex organisms are embedded in a fluid matrix constituting an internal environment the constitution of which normally remains constant—a condition referred to as homeostasis or homeokinesis. Claude Bernard (1878) was the first to realize this truth, crystallized in his expression—

La fixité du milieu intérieur est la condition de la vie libre.
This theme was further developed by Cannon (1930), and later was the subject of discussion by Barcroft (1934). Mechanisms have been developed in the body whose sole object is the preservation of this constant. As stated by Cannon "The membranes which separate the vascular from the interstitial compartment and those which separate the latter from the intracellular compartments have peculiarities of permeability which maintain an unequal distribution of solutes in the three compartments." Exchanges in one or other direction are effected by vascular adjustments controlled, it is now generally recognized, by a "capillariomotor system," independent of the rest of the vasomotor system, by hormones, by local metabolites, etc.

The capillary system is therefore of prime importance, its welfare essential for the maintenance of the tissues in health, yet when Krogh (1929) published his monograph, *The Anatomy and Physiology of the Capillaries*, he remarked "The capillaries constitute the most essential part of the circulatory system" but added, "They have been neglected in an extraordinary way."

Much work has been done on the subject by a number of investigators, including Dale (1918-19), Krogh (1929), Lewis (1927), Bordley *et al.* (1938), Wright and Duryee (1933), the Clarks (1931-2), Sandison (1928), Cobb (1927-32), Zwiessach (1937-40), Sanders, Eberl and Florey (1940) etc., but space forbids anything but mention of their names.

I cannot here go into more detail, but must be content to point out how great is the part played by the capillary system, how many its functions in the economy of the organism, and how vast its field of action.

To give a single example from Krogh, he calculated that the capillaries supplying the muscles of an adult man which number 1,350 per square millimetre in transverse section, would measure 100,000 kilometres if joined end to end—i.e., would go twice round the world. Their surface would be 6,300 square metres. A simple calculation shows that if packed into a solid mass these endothelial cells would form an organ of

sonic size. The time has passed when the capillary endothelium was looked upon by the older physiologists as a passive, inert membrane, like a piece of gelatin governed only by simple physical laws. It is a tissue of great activity; it must need a considerable amount of energy in order to carry on its functions yet nothing is known concerning the metabolism and respiration of its cells.

Many may have tacitly taken it for granted that a tissue which is in direct contact with the blood stream had merely to pick up what it wanted without any vital process being involved, but this is not consonant with Nature's methods. It may be assumed—and I think the assumption is warranted—that the endothelial cell respires in the same way as the cell of any other tissue and that for its metabolic processes it must be supplied with sugar, oxygen, and all those other elements essential for cell life including riboflavin. Having made this assumption I am going to suggest that in the event of a deficiency in any one of these elements or in some one of the elements—namely, riboflavin—the capillary endothelium will be one of the first if not the first, of the tissues to suffer the effects of interference with normal respiration and metabolism. The result of this anoxia, in the wide sense of the term, upon the capillaries is a derangement of function which I shall refer to as "capillary dysergia," with the development of loss of tone, dilatation and decreased flow. This in turn leads to a disturbance in the surrounding *milieu intérieur* and so to a metabolic disorder of the cells of the neighbouring tissue.

It is generally agreed that the relative number of capillaries is such, and their disposition so devised, as to accommodate the metabolic needs of each tissue in the body. This being so, I have suggested that manifestations of riboflavin deficiency will become apparent first in those tissues with high metabolic activity and a high degree of capillarity. By capillarity I mean the relative number of capillaries normally present in a tissue. The signs will be capillary dilatation, obviously only to be determined in some tissues, the symptoms, impaired nutrition and impaired function of the tissues. It is upon this basis that I propose to offer an explanation of the nature and distribution of the signs and symptoms of hyporiboflavinosis.

(To be concluded)

TWO YEARS OF MILITARY PSYCHIATRY IN THE MIDDLE EAST

BY

H. B. CRAIGIE, M.B., D.P.M.
Lieut Col R.A.M.C.

In his article "Three Years of Military Psychiatry in the United Kingdom" (*BMJ* 1943 1, 1) Brigadier J. R. Rees has presented a general survey of Army psychiatry in this country, setting out its development and present tendencies. The present article gives a survey of Army psychiatry in its application to an expeditionary force engaged in an active theatre of war.

Development and Organization

The development of a psychiatric organization in the Middle East dates from the appointment in Aug. 1940, of a Consulting Psychiatrist to the Middle East Force. The entry of Italy into the war in May, 1940, had marked the inception of a new phase in the military situation of the Middle East. With the arrival of large and constantly increasing drafts of men from all parts of the Empire it became evident that the provision of an adequate and organized psychiatric service was likely to become a matter of some urgency. The history of the psychiatric organization in the Middle East originating as above, has been one of continued expansion. Before the arrival of the Consulting Psychiatrist no special facilities existed for the diagnosis and treatment of psychiatric cases which were of necessity admitted either to the ordinary medical wards of a general hospital or as in the case of psychotics, to small observation wards attached to two or three of the established military hospitals.

The situation in Aug., 1942, provided an interesting contrast. In place of the original limited observation wards there were by that date specialized psychiatric hospitals, centres, and psychiatric sections of convalescent depots. In addition to the original Army Consulting Psychiatrist, who, with the help of two specialists in psychiatry, was responsible for all the psychiatric cases arising not only in the Army but also in the Royal Navy, R.A.F., and the various Dominion and Allied troops, there were thirteen Army specialists in psychiatry and at least an equal number of graded specialists and medical officers solely engaged in psychiatric work, as well as psychiatrists attached to the other Services and the Dominion Forces.

In any consideration of the organization and work of the psychiatric services in the Middle East it is essential to realize the extent of the area concerned and the associated difficulties in travel and communication. The area included Egypt, Palestine, Syria, the Sudan, Eritrea and Abyssinia, Libya, Cyprus, and originally Iraq and Iran. The vastness of this area bore a direct relation not only to the problems arising in establishing a co-ordinated and organized psychiatric service itself but also to the problem of arranging for the evacuation of psychiatric cases; for example, the evacuation time between the forward areas in the Libyan campaign and a suitable base hospital or centre was rarely less than seven days, and was generally associated with a maximum degree of mental and physical stress and strain.

A second problem of very considerable practical importance was the wide diversity of races and nationalities encountered. During the course of 12 months in one centre alone, patients of the following nationalities were admitted (in addition to British and Dominion troops): French, Greek, Polish, Czechoslovak, Russian, Cypriot, Maltese, Palestinian (Jewish, Arab, and Christian), Turkish, Mauritan, Seychelles, Chinese, Portuguese, and various African races, including Kaffirs, Basutos, Bechuanas, Matabeles, Zulus, Swahilis, and Abyssinians. In addition German and Italian prisoners of war were admitted for treatment.

Incidence

The actual numerical incidence of psychiatric breakdown was considerable; but, judged in relation to the total numbers involved and to the extreme degrees of mental and physical stress and strain present in so many cases, it was perhaps surprising—as Surg. Capt. Curran has recently pointed out in reviewing naval cases—not that so many but rather that so few breakdowns occur. It is clearly undesirable at this stage of the war to give statistics of actual figures in detail, but it may be stated that the annual incidence of neurosis in the Middle East during the last two years has shown no significant variation from the figures obtaining in the last war.

It must always be remembered, however, that statistics and percentages by themselves give a very partial and inadequate picture of the situation as a whole. The amount of time and difficulty involved in the handling, evacuation, and treatment of psychiatric casualties is often out of all proportion to the actual numbers involved; and the potentially "infective" nature of psychiatric casualties is always a factor of considerable importance. There can be little doubt that if adequate selection of personnel had been employed before men were sent to a battle area a very marked decrease in the incidence of neurotic breakdowns, and a great improvement in the prognosis when breakdown did occur, might reasonably have been expected.

The aetiology of psychiatric breakdown may best be considered under the two main headings of predisposing and precipitating factors.

Predisposing Factors

(a) Psychopathic Constitution

The very great importance and significance of a psychopathic constitution, both as an aetiological and as a prognostic factor, was shown repeatedly throughout the period under review. An analysis of all admissions to one psychiatric centre during a six-months period showed that no less than 21.7% of neurosis and 23.8% of psychosis cases had suffered from a previous neurotic or psychotic breakdown: these percentages were even

more marked in regard to officers, among whom, in the same series, 46.2% of neurosis and 37.5% of psychosis cases had had a previous breakdown. A further analysis of the same series showed that, in addition, 38% of all anxiety neurosis and 33% of all hysteria cases showed evidence of markedly abnormal personalities before their present breakdown. The term "markedly abnormal" is here used advisedly: all these patients had shown evidence of relatively gross psychopathic traits in their previous histories, usually extending over a period of many years and dating from childhood and adolescence. These psychopathic traits were all of an accepted, obvious, and easily recognizable type, such as would have been clearly revealed by any careful case history; they did not rest on any abstruse or controversial psychopathological theory.

The significance of a psychopathic previous history was shown at every stage of the individual's military career. Many of these men broke down under the initial stress of embarkation for over-seas or during the voyage; and many required admission to hospital immediately upon arrival in the Middle East (thus 36 cases were admitted direct from convoys to one centre alone during the second quarter of 1942). A much larger number of individuals of this type broke down within a few weeks of arrival, and were completely unable to readjust themselves to the conditions of overseas service. An even larger proportion broke down before ever reaching a forward area. Cases of neurotic breakdown can conveniently be differentiated into cases of "battle neurosis" (cases breaking down under the stress of battle) and "neurotic sick" (cases occurring without relation to battle stress). An analysis of one large series of cases showed that 79% of the neurotic sick had a bad previous history, as against only 22% of the battle neurotics.

These factors are of the highest importance, because in the elimination of the misfits, of the chronic neurotics, and of the psychopaths lies the most direct and most hopeful method of prevention available to us. Very little can be done in an actual battle area to limit or alleviate the stresses and strains or to alter the adverse environment; and, given sufficient stress and strain, any person may break down. We can, however, and we should, sift out those who are likely to break down early—the weaker brethren, those who can cause difficulties and disharmonies and perhaps even disasters out of all proportion to their numbers, and whose presence constitutes a continued if only a potential menace to the morale of the group as a whole.

(b) Psychopathic Family History; (c) Morale

The significance of a psychopathic family history, although rather more difficult to assess, should not be underestimated; approximately one in five of all admissions in the above series showed evidence of a markedly psychopathic family history.

The question of morale, with all its implications, was of course of fundamental importance: faulty morale, indifferent training, or poor discipline provided a fruitful soil for the development of psychiatric breakdown. The series of African campaigns has proved beyond all shadow of doubt that half-trained, irresolute, incompetent men are useless in modern battles. The modern soldier, more perhaps than ever before, has got to be alert, competent in the use of arms of several varieties, self-sufficient, and resolute in situations in which he must act alone—situations often encountered by the need for dispersal.

Precipitating Factors

(a) General

Domestic Separation.—The disruption of family life, the impossibility of obtaining home leave, and the prospect of indefinite separation from the home and family were factors of the greatest importance, especially if—as was often the case—there was associated anxiety over illness of relatives, financial stress, rumours of marital infidelity, or news of enemy air raids near the individual's home. Much anxiety was felt throughout the command during the Battle of Britain, and quite a large number of serious breakdowns were precipitated by the news of certain towns at home having been bombed. These facts are perhaps of additional significance in the light of the recent R.A.F. offensive against the Ruhr. In this

connexion the very great importance of a regular and reasonably rapid mail service was in constant evidence—delay, irregularities, or non-arrival of mail were potent causes of anxiety and depression even in the most stable personalities.

Climate.—The trying climatic conditions prevailing in the Middle East—extremes of heat, shortage of water, flies, sand, and dust—were all important precipitating factors; on the other hand, it should be stressed that the effect of climate and temperature is essentially indirect, and is not in itself a direct cause of psychiatric breakdown: such terms as "tropical neurasthenia" are misleading, and are best avoided.

(b) Battle Stress

The term "battle neuroses" was, as already stated, applied to those cases of neurosis precipitated by the actual conditions of battle. Any of the above more general factors were, of course, liable to be associated in varying degree in the causation of battle neuroses, especially when combined with prolonged loss of sleep and extremes of physical stress and fatigue, and, conversely, the fact that the breakdown occurred during battle does not necessarily indicate that these battle conditions were in themselves more than incidental factors in the causation. In the great majority of cases of battle neuroses, however, the immediate precipitating factors could be accepted as being the actual conditions of enemy action.

The nature of the battle stress varied considerably with the theatre of operations concerned. In many cases the first symptoms of breakdown had appeared after the campaigns in Norway and France; in others, in East Africa or Syria. The majority of cases originated during the various Libyan campaigns or during the evacuation of Greece and Crete; or, in naval cases, during the course of the long and arduous naval operations in the Eastern Mediterranean. Without any question the most important single precipitating factor in the production of battle neurosis was continued dive-bombing or machine-gunning from the air, in the absence or relative absence of aerial protection, and most particularly when experienced under conditions of inactivity without the possibility of retaliation. The importance of this form of attack was shown repeatedly, and was out of all proportion to the actual number of fatalities caused.

The importance of the above factors was most pronounced during the earlier stages of the campaign, especially during the evacuation of Greece and Crete.

Table I shows the percentage of total cases (in a series of 633 consecutive admissions to one psychiatric centre) resulting from battle stress in the varying types of neurosis: figures for certain psychotic reactions, associated in origin with severe battle stress, are given for purposes of comparison.

TABLE I

Anxiety neuroses	63.2
Hysteria	26.8
Other neuroses	19.0
Schizophrenia	23.4
Manic-depressive psychosis	7.7

The actual degree of battle stress varied, of course, very widely, ranging from sporadic high-level bombing to prolonged shelling, repeated immersions (in naval cases), and similar forms of severe stress. It is, however, of importance to note that breakdown from battle conditions was throughout the period relatively uncommon, and has become increasingly less frequent.

Clinical Types

Physical Exhaustion.—A recent analysis of battle casualties evacuated from a forward area showed that four out of five cases classed as "N.Y.D.N." were in reality cases of fatigue and exhaustion, and were without any deeper psychiatric significance. The importance, from the point of view of both prognosis and disposal, of establishing the true nature of these cases has been recognized in the revised *Nomenclature of Mental Diseases*, now in official use in the Army.

Neuroses.—The largest group of cases included under this title were those of anxiety neurosis, which accounted for over two-thirds of the total neurosis cases. Hysterical reactions occurred less commonly, accounting for approximately 20% of total neurosis cases. Experience in the Middle East therefore confirms the experience of other observers—that hysterical conditions are very much less frequent in this than in the 1914-18 war.

Anxiety Neurosis.—In the acute anxiety reactions precipitated by battle stress, disorders of behaviour were often prominent: acute panic reactions were common, often associated with episodes of extreme aggression or even violence. Semi-stuporous states were also of frequent occurrence. A querulous, resentful, anti-social attitude was often found in anxiety neurotics under treatment. Table II shows the percentage incidence of the main presenting symptoms in a group of 215 anxiety neurosis cases admitted consecutively to one centre.

TABLE II

Depression	43.8
Anxiety	47.0
Headaches	42.3
Insomnia	38.3
Cardiovascular symptoms	30.5
Gross tremors	25.8
Gastro-intestinal symptoms	22.0
Acute panic reactions	22.0
Lassitude	19.7
Associated hysterical reactions	16.5
Phobias	11.2
Lack of concentration	11.2
Memory defects	4.7
Frequency of micturition	3.7

The above analysis makes no pretence to scientific accuracy either in terminology or in other ways, but it is perhaps of interest as a rough index of the relative frequency of the common symptoms. Two points of interest emerge from a study of these figures—the predominance of depression as a symptom, and the relative infrequency of psycho-omatic symptoms of the cardiovascular type. The importance of depression as a presenting symptom was, in fact, even more marked than the above figures suggest, inasmuch as a certain group of cases usually diagnosed as anxiety neurosis had in the above series been classified separately as "reactive depression."

Hysteria.—Table III shows the relative frequency of occurrence of the main symptoms in a group of 71 hysterical cases admitted consecutively to one centre.

TABLE III

Amnesia	21.0
Convulsions	19.6
Paresis or paralysis	18.2
Fugues	14.0
Blindness	5.6
Vomiting	5.6
Involuntary movements	4.2
Somnambulism	2.8

The cases of dissociation—amnesia and fugues—thus constitute the largest group (35%), and are commoner than cases of the conversion type.

Psychopathic Personality.—These cases accounted for approximately 6% of the total neurosis admissions to one centre; as might be expected, however, the difficulties presented by individual members of the group in treatment and disposal more than compensated for any numerical inferiority. It is notable, and in keeping with experience, that less than 10% of these cases were associated in origin with actual enemy action. One special group of these cases—the homosexuals—presented problems of especial difficulty in the Middle East, in relation both to treatment and to disposal; apart, however, from stressing the inadvisability of sending innate homosexuals (if diagnosed) to the Middle East or to any similar overseas station, it is not possible here to enter into any more detailed discussion of the clinical aspect of these cases.

Obsessional Neurosis.—Fully developed obsessional states were rare, but, when they did occur, were usually of unfavourable import and unlikely to respond to ordinary forms of treatment.

Psychoses.—The total number of psychotic cases admitted to hospitals and centres was considerably in excess of expectation. This excess could be explained by various factors—the most important being the wide variety of nationalities encountered, including large numbers of coloured troops, in whom the correct assessment and diagnosis of disorders of behaviour presented many difficulties.

Schizophrenia.—This was by far the most frequent psychotic reaction, accounting for rather more than 50% of the total psychotic cases. As noted during the last war, schizophrenic reactions developing during war were often of a more benign type than those developing under the more ordinary conditions of civil life.

Manic-depressive Psychosis.—Cases of manic-depressive psychosis accounted for approximately 30% of all psychotic cases; mania and melancholia were the presenting phases in an approximately equal number of cases.

Other Psychoses.—Psychoses attributable to infection (either acute or chronic) were uncommon. A very small number of cases of cerebral malaria occurred, and only one case of dementia paralytica (a Cypriot) was found in a series of over 1,200 admissions to one centre. Mental symptoms associated with heat hyperpyrexia were seen in a few cases, but in only one case in the above series was there any serious residual mental abnormality. A large number of

cases of pellagra were seen on one occasion among native troops; it was difficult to assess the degree of mental abnormality, if any, in these cases owing to language difficulties, but there was no evidence of behaviour disorders or gross mental change. Alcoholism in its various manifestations was fairly common, ranging from acute alcoholic episodes to chronic alcoholism and delirium tremens. Cases of psychosis in association with drug addiction were rare, consisting mostly of hashish addiction among the local native troops. A stuporous state lasting from 24 to 48 hours, and resulting from the consumption of "doped" alcohol in certain of the local establishments, was at one time fairly common, and led at first to some difficulties in diagnosis. Although epilepsy was fairly common, epileptic psychosis was rare.

Head Injury.—Psychosis associated with cerebral trauma was uncommon. The series of 633 admissions to one centre included only eight cases of post-traumatic personality change; this figure is, however, to some extent misleading, as the great majority of head-injury cases were admitted to and treated in the special neuro-surgical centre, and in consequence only cases with gross mental change were likely to be admitted to a psychiatric centre. From the somewhat restricted experience of post-concussional and head-injury cases gained at a psychiatric centre, the general impression was obtained that such cases are unsuited for service in tropical or subtropical climates.

Intellectual Defect.—Cases of congenital mental deficiency or of mental dullness and backwardness were unduly common, especially during the earlier part of the period under review. In the above series of 633 admissions there were 14 cases of mental dullness and backwardness and 27 cases of mental deficiency; of the mental defectives 23 were of the higher-grade, 2 of the medium-grade, and 2 of the lower-grade feeble-minded type. In seven cases there was a long record of delinquency and three had been certified as mental defectives before enlistment. The total number of mentally defective or dull and backward cases was very much greater than that given above, as many such cases were disposed of as out-patients and did not require admission to hospital. The following example provides a rather significant instance of this:

Twenty-seven men out of a draft of 80 posted to a certain unit were considered by the commanding officer as unfit to carry out the specialized duties required in this unit. On the advice of the unit medical officer they were referred to a psychiatric centre for an opinion. As a result of a careful and detailed investigation of each case, combined with intelligence tests, 7 were found to be higher-grade feeble-minded defectives; 11 were mentally dull and backward, and a further 6 were of subnormal intelligence, and unfitted for any form of specialized training.

Delinquency.—An increasingly large number of delinquents were referred to psychiatric hospitals or centres for an opinion, ranging in degree from the mildest cases of "absence without leave" to hardened recidivism. The commonest type of case, and the type that presented the greatest difficulty in diagnosis, was that in which a state of amnesia or fugue was put forward as a defence for absence without leave or desertion.

Malingering.—Deliberate malingering was in our experience rare; there were, however, the usual number of somewhat dubious borderline cases, which caused certain difficulties in diagnosis.

Treatment

In a general survey of this nature it is possible to give only a very brief summary of the various forms of treatment employed, and the principles underlying their application. In no field of medicine, and more particularly of military medicine, is the dictum "Prevention is better than cure" more applicable than in the handling and treatment of cases of psychiatric breakdown. It is far too late to start preventive measures—to develop selection of personnel, in other words—in an actual theatre of war; the best selection in these circumstances tends to be a haphazard and fortuitous process, and more often it will resemble a process of salvage rather than selection.

Selection, then, should start before entry into the Army; it should continue throughout the stage of training; and it should apply particularly to all drafts for overseas service, most particularly of all for overseas service in an active theatre of war. It should always be remembered that a soldier may be called into action the moment he arrives in a new country, often with little or no possibility of adaptation to a strange land, to a trying climate, or to the stresses and hazards of active warfare. It is useless to send men overseas where their previous history indicates that early breakdown is likely—and this applies not only to cases of neurosis but to chronic delinquents: it was the somewhat bitter experience of most observers—combatant officers as well as psychiatrists—that the

character of the delinquent does not undergo any curious reformation or metamorphosis on leaving these shores. However careful selection may be, a certain number of cases of psychiatric breakdown will continue to occur, although here again much will depend on the general morale and *esprit de corps*, and on the training and efficiency, of the unit as a whole.

The conditions of present-day warfare, especially in the desert, present much difficulty in the handling and treatment of psychiatric casualties. Evacuation is lengthy, involved, arduous, and exacting; opportunities for adequate treatment in the field are few and the difficulties of such treatment may seem at times overwhelming. On the other hand, the further back a psychiatric casualty is evacuated the less is the probability of his ultimate return, the worse is the prognosis as regards his ultimate efficiency as a soldier, and the more serious may be the effect upon the other members of the unit.

Treatment therefore must be immediate; its application must be measured in terms of minutes rather than hours, and of hours rather than days. It must be immediately effective and it must remain effective. It must be simple, uncomplicated and at the disposal of every R.M.O. It is unlikely the specialist advice will be available in more than a small percentage of cases, and the R.M.O. must therefore have working knowledge of their diagnosis and treatment. The only feasible method of immediate treatment is by physical measures; the cardinal factor throughout is rest, and in these circumstances rest can only be procured by full sedation. The choice of sedative depends on various factors, one of the most important naturally being the range of drugs actually available. Alcohol and morphine are of use in emergencies, but the small bulk and ease of administration of the barbiturates (e.g. barbitone or phenobarbitone) make these drugs the most generally acceptable. Intramuscular injections should be given where necessary. The dosage must be adequate; too little is usually given, and it is important that adequate sedation be maintained throughout the period of evacuation to the base, if such evacuation should prove necessary.

The methods of treatment applied in the later stages do not differ materially from those applied to the neuroses in general. Prolonged narcosis was used extensively in the treatment of acute anxiety states in base centres and hospitals, and was found in most cases to be the method of election. It is of some importance to note that prolonged narcosis presents certain dangers in tropical or subtropical climates, and several cases of hyperpyrexia occurred during treatment, presumably due to disturbance of the heat-regulating mechanism.

The intravenous injection of a suitable barbiturate, reinforced by suggestion and the appropriate psychotherapeutic measures, proved a most valuable form of treatment in effecting the removal of conversion symptoms or the restoration of memory in hysterical amnesias or fugues; in many cases the early application of these measures restored function and allowed of return to duty without evacuating the patient to the base.

Emphasis has been laid above on physical methods, which indeed, provide the only practicable form of first-aid treatment in the great majority of cases in a forward area. In the psychiatric hospitals and centres at the base a much wider scope and range of treatment was available and used. Psychotherapy was employed—usually in its simpler forms—in all cases, and under the general heading of psychotherapy may be included the invaluable help rendered in many cases by the chaplains of the various denominations and by such organizations as the S.S.A.F.A. Fully equipped occupational departments were provided in each centre as well as the various recreational activities and excellent libraries provided by the B.R.C.S. The importance of semi-military training in the treatment of neurosis cases, not only for its own sake but as a preparation for return to duty, was recognized, and such training was used to an increasing extent. An insistence on a reasonable degree of military discipline in the treatment of neurosis cases in general was considered of great importance and produced very beneficial results.

Prognosis: Results of Treatment

It was decided at the beginning of the period under review that as a matter of general policy it was of the utmost impor-

tance to retain, so far as was possible, all cases in the command on at least some form of duty, and to confine evacuation out of the command to psychotic cases and those neurosis cases in which, for various reasons, the ultimate prognosis was regarded as very unfavourable. As a result of practical experience this policy was further developed, and it was decided that psychotic cases, after recovery and if considered suitable on other grounds, should also be retained in the command. This rather radical revision of policy in the case of psychotics was adopted only after careful consideration, but has already proved successful in practice.

The following statistics are of interest in assessing the prognosis and the results of treatment. In a series of 350 consecutive cases of neurosis discharged from one psychiatric centre during the six-months period July to Dec., 1941, 71.5% were returned to duty (53.7% to full, 17.8% to base duties); the average duration of stay in hospital for these cases was 25 days. During the three-months period April to June, 1942, 625 neurotic and 216 psychotic cases were discharged from one hospital; of the former group 92% were returned to duty (61% to full, 31% to base duties); of the latter 70% were returned to duty (48% to full, 22% to base duties).

Follow-up.—A careful follow-up system was employed throughout the period under review. An analysis of the results of the follow-up suggested that not more than 5 or 6% of cases required readmission to hospital or centre; this figure compares satisfactorily with those given for the war of 1914-18. It should be remembered that such cases of relapse as do occur do not necessarily represent a pure loss to the Services; during the interval before relapse occurs they may be, and in very many cases were, of the greatest value to the Army.

Conclusions

The results obtained during the two-year period under review have been reassuring, and the high proportion of patients returned to duty has demonstrated the practical value of specialized psychiatric units and treatment. The indifferent quality of many of the drafts sent over-seas was often only too obvious, and has been indicated in some detail in the earlier sections of this paper; not only were many of these men unsuitable for service over-seas, but in many instances they were, as has been stated elsewhere, "candidates for hospital treatment on enlistment." It is clear that the efficiency of an expeditionary force must suffer if it includes large numbers of officers and men who, by virtue of their previous histories, are likely to develop a psychiatric breakdown.

The value of an organized system of personnel selection was thus shown in a very practical form throughout this two-year period, and it is difficult to avoid the conclusion that, had the system of personnel selection which is now applied to all recruits on joining the Army been applied from the beginning of the war, a very large proportion of the psychiatric casualties in the Middle East would have been avoided.

Summary

An account is given of the organization and development of the psychiatric service in the Middle East Force.

Details of the incidence of psychiatric breakdown in the Middle East Forces are provided.

The various aetiological factors are discussed, with particular reference to the significance of a psychopathic previous history in determining the likelihood of future breakdown.

A brief account is given of the various types of clinical cases encountered.

Details are presented of the main forms of treatment employed.

An analysis is given of the results of treatment, with details of the percentages of cases returned to duty.

The very great importance of personnel selection is stressed.

I wish to record my gratitude to Brig. G. W. B. James, M.C., Consulting Psychiatrist, Middle East Force, to whose inspiration, energy, and wide understanding the organization and developments described above are due, for his advice in the preparation of and his permission to publish this paper; to Brig. H. A. Sandiford, M.C., Director of Army Psychiatry, and Brig. J. R. Rees, Consulting Psychiatrist to the Army, for their continual encouragement and assistance; and to the medical and nursing staff and the R.A.M.C. personnel of No. 1 Psychiatric Centre, M.E.F., whose enthusiasm and co-operation made possible so many of the results detailed above.

DIAGNOSIS AND TREATMENT OF LESIONS DUE TO VESICANTS

BY

W. E. CHIESMAN, M.D., M.R.C.P.

Medical Officer, Ministry of Supply (Chemical Defence)

In spite of the increasing air superiority of the United Nations the possibility of gas being used in this war cannot be ignored. The enemy might use it during any critical stage of military operations. Moreover, it would be dangerous to assume that we shall never see any cases suffering from the effects of gas, as they may result from accidents which occur from time to time. Methods of defence rapidly overtake new and unexpected methods of attack, so that no weapon ever again achieves its initial success. Had the Germans appreciated the success of their first gas attack in the last war the final result might have been very different. Should gas be used we can expect it on a large scale, with indiscriminate mixing of blister, choking, and harassing varieties—the characteristic smell possibly being disguised—plus high-explosive and incendiary bombs. With this in mind, it is important to simplify the anti-gas teaching, so far as is possible, reliance being placed on a few common-sense principles.

The gas discipline of the Services has received a great deal of attention and is so good that nothing but a nuisance effect is likely to be achieved against them. Civilians, however, who have not received special training are likely to be far more vulnerable, and the effect of panic must not be overlooked. It is essential for the able-bodied to help themselves by means of the gas-mask, removal of clothes, and immediate treatment with ointment, leaving the official anti-gas parties free to handle those who cannot help themselves.

The first attack may be at night, and if the action of the gas is a delayed one its presence may not at once be recognized. In consequence, the medical profession will be faced with a large number of cases suffering from lesions of the eyes, respiratory tract, and skin, some hours after the time for effective prophylactic treatment has passed. Subsequent attacks will be countered more easily, as the population will be prepared and suitable prophylactic measures can be taken immediately.

In order that protection may be available at the earliest moment the clinical diagnosis of the first cases is most important, and will largely be the doctors' responsibility. If the doctor suspects gas has been used he should at once get in touch with the nearest A.R.P. Report and Control Centre, whose responsibility it is, so as to obtain confirmation from their Gas Identification Officer. We must remember that the lethal effects of any gas are most commonly produced by inhalation, the next most serious danger being injury to the eyes. Skin lesions, although a major nuisance, will cause less loss of life than similar conditions due to thermal burns, and are certainly less severe than the injuries caused by high explosives. The gas-mask must always be the first line of defence, and it is important never to lose sight of this when devising other methods for prophylaxis. The immediate removal of contaminated clothing is equally important, as it reduces the risk of injury to the person concerned and the possibility of spreading the material to others.

MUSTARD GAS

Prophylaxis

Eyes.—Constant protection of the eyes by the eye-shield or gas-mask is of first importance. If liquid should enter the eye immediate mechanical removal by copious washing with water, saline, or other bland fluid is essential. If carried out within two to three minutes of contamination it will probably save the eye; if delayed for longer it is of little value. Care must be taken to see that material from the surrounding skin is not washed into the eye. However, if the eye is affected only by vapour, washing will do more harm than good. So much stress has been laid on the importance of early irrigation of the eyes that there is a tendency to forget that it is equally important to get rid of contaminated clothing. If help is available the two should be done coincidentally.

General Principles for Skin Cleansing.—Three methods are available—mechanical removal, dilution and removal by washing, or chemical neutralization—before the vesicant can penetrate and produce its local and systemic effects. As the effective dosage of liquid

vesicant is very small mechanical removal can never be completely efficient. Washing must be prolonged, with many changes of water, and the danger of spreading the vesicant rather than eliminating it is very great. In many cases the gas-mask must be removed in order to wash the whole body effectively, with consequent risk to the eyes and chest. Chemical neutralization must therefore be the method of choice, followed, if possible, by bathing.

In the last war mustard gas was the vesicant used and bleach cream the most readily available antidote. At the beginning of this war the authorities took steps to provide facilities for treatment by bleach cream on a large scale. However, the difficulty of doing this comprehensively is obvious. To be completely effective the bleach cream must be freshly prepared and be applied with the bare hands immediately after contamination. It is equally important to remove it by washing, as it is a severe skin irritant—a point which is often overlooked. Another disadvantage of bleach cream is that it is not readily portable and does not keep. Subsequently, anti-gas ointments were introduced for use in the field, as they could be carried easily and had good keeping qualities. Anti-gas ointment No. 1 is excellent against mustard gas, but is of little use against lewisite. Because of its skin irritancy it has to be washed off after use. It has been rendered obsolete by better ointments which deal with both mustard gas and lewisite. Anti-gas ointment No. 2, which is on sale to the public, is very effective, but becomes irritating if covered with clothes or bandages. Subsequent numbers now being prepared, but not at present available to the public, have the advantage of being innocuous to the skin, though not more effective than No. 2.

When handling a contaminated case there are two points to be considered: first, the avoidance of injury to the contaminated person; and, second, the prevention of transference to others. Avoidance of injury will depend on the immediate removal of clothing if it has liquid on it or has been worn in an atmosphere containing vesicant vapour, followed by suitable treatment of the contaminated skin. Transference to others will be avoided by suitable treatment of discarded contaminated clothing. The danger of transference from the skin of a patient is negligible unless actual liquid is visible. In fact, if you cannot see anything on the skin it is safe to assume that absorption or evaporation has taken place and the patient can be handled with comparative immunity, particularly if the hands are first protected with anti-gas ointment. No chemical neutralization should ever be carried out if actual lesions are developing, as such treatment will increase the severity of the final lesions; at this stage careful washing with an antiseptic solution is the only useful treatment. The condition of the patient is of first importance, and cleansing only a secondary consideration: better the contaminated living than the decontaminated dead.

Hair contaminated by liquid mustard gas should be treated with bleach cream followed by washing (or by rubbing in anti-gas ointment, which may then be washed off, or removed by kerosene if this is available). In some cases, to facilitate treatment it may be necessary to remove the hair. If the patient is injured and contaminated, clothing may be removed and ointment applied to the skin, always bearing in mind the danger of increasing the shock. Removal of mustard gas from the damaged tissues is a problem that will have to be left in the hands of the surgeon. It is worth while to remember that neutral hyperchlorite solution (1% available chlorine) has some value as a decontaminant.

Diagnosis

It must be borne in mind that exposure to vapour of vesicant gas affects the organs in the following order of susceptibility: eyes and alimentary tract, respiratory tract, skin, general system. The severity of the lesion is dependent on the concentration and the length of exposure, so that liquid for a short time, or vapour for a long time, can produce identical effects. Without protection or prophylactic treatment multiple injuries of varying degrees will occur.

Eyes.—The initial effect of mustard gas in the eye is negligible even on the entry of liquid. The onset of symptoms occurs a few hours after exposure. The eyes become irritable and severe pricking pain develops: lacrimation, photophobia, and blepharospasm are the usual symptoms of mustard gas keratitis. The physical signs usually seen are redness and swelling of the lids, congestion of the conjunctiva, and corneal haze, which can be seen by the naked eye in the more severe cases, but which is visible only by slit-lamp examination in the milder ones.

Alimentary Tract.—Epigastric pain, vomiting, and diarrhoea occur coincidentally with the eye symptoms, but tend to settle rapidly in most cases.

Respiratory Tract.—Sore throat develops in 12 to 24 hours after exposure, with a dry irritating cough. Subsequently vesicles may appear on the soft palate and the fauces. Later the voice is lost, and in bad cases ulceration of the trachea and upper bronchi follows. Bronchopneumonia and any form of septic lung condition (bronchiectasis, lung abscess, etc.) may occur in severe cases. It is important, if anaesthesia is contemplated, to remember the delayed

action on the respiratory tract. The use of ether at this stage will certainly increase the severity of the lung condition when it declares itself.

Skin.—Irritation and redness appear 6 to 8 hours after exposure, followed by erythema, marked oedema, and finally vesication. In vapour exposures the genitalia are particularly vulnerable. In the most severe skin cases large white areas like pigskin, with surrounding groups of vesicles, are encountered, the most characteristic feature being the wide area of erythema and oedema surrounding each blister. Small blisters may at first appear and later join together to form large flabby bullae which are easily ruptured. Crops of blisters may occur up to the tenth day after exposure. Invariably there is a characteristic purplish discoloration of the affected skin and itching. Brown pigmentation may occur after healing and persist for a long time. When large areas are involved a condition closely resembling shock, with a low blood pressure and haemoconcentration, is not uncommon.

Systemic Effects.—In severe cases the bone marrow may be affected, with development of an agranulocytic type of anaemia. Damage to the liver and kidneys is also recorded.

Treatment

Eyes.—Immediate and copious irrigation of the eyes is of the utmost importance in the event of liquid contamination, and has already been stressed under "Prophylaxis." Once the initial irrigation has been carried out it should not be repeated, either for liquid or for vapour contamination, as it does more harm than good. If the eye is painful relief is best obtained by the use of a mydriatic—either atropine 1% or hyoscine 0.5%—instilled two or three times a day until the pupil is fully dilated, whereupon it should be stopped unless relapses occur with contraction of the pupil. If dilatation does not take place readily a specialist's advice should be sought. Bandaging the eye should be avoided, but the use of a paper or cardboard shade is comforting. Sulphacetamide (albulid) drops may be used in the early stages as they minimize the risk of secondary infection and are comforting, but once full dilatation of the pupil has been attained the pain disappears. Local analgesics are best avoided, but a central narcotic may be indicated in the early stages, before dilatation of the pupil. Antiseptics should be avoided as they tend to injure the already oedematous corneal epithelium. The copious discharge, which has the appearance of pus but in fact rarely contains bacteria, will usually disappear in 3 to 4 days if the pupils are kept dilated. Crusts round the lids can be removed with cotton-wool swabs and paraffin applied along the lid margins to prevent sticking. The psychological effect of an injury to the eye is considerable, so every effort should be made to reassure the patient by showing him that he has not lost his sight and by persuading him to return to a normal life at the earliest opportunity. The subsequent treatment of the complications should always be in the hands of an ophthalmic specialist.

Alimentary Tract.—As there is no specific treatment for the abdominal pain and vomiting they must be symptomatically dealt with.

Respiratory Tract.—The cough may be controlled with codeine and inhalation of tinct. benz. co. The use of sulphonamides should be reserved for the treatment of infective lung conditions. It is probably unwise to employ them prophylactically, as the majority of mild cases make an uninterrupted recovery.

Systemic Effects.—Particular attention should be paid to the condition of the blood; as with any extensive burn, haemoconcentration will call for plasma. The onset of agranulocytosis is marked by an early leucocytosis followed by a leucopenia which may appear as quickly as the third day after exposure. If the use of sulphonamides is contemplated blood counts must be done repeatedly to make certain that agranulocytic changes are not taking place. During administration the fluid intake must be sufficient to ensure the passage of 1,000 c.cm. of urine a day.

Skin.—There is nothing mysterious about the treatment of the skin lesions. They are slow to heal, prone to sepsis, and respond badly to any form of tanning treatment. As is the case with the treatment of thermal burns, avoidance of sepsis, rest of the injured part, control of oedema, and relief of pain are the four principles which must be constantly kept in mind. Resort to any form of prophylactic ointment when a lesion is visible is to be condemned. The exudate from the blister is innocuous. Before starting treatment remove hair with clippers. The question of what should be done with the blistered skin is a difficult one and must depend on the condition of the blisters when first seen. Leaving the skin intact has the advantage of reducing pain, preventing excessive exudation and shortening the time of healing. There is no doubt about its value in small uncomplicated cases. However, the presence of dead skin in the later stages of treatment, or of skin that is detached and not covering the raw area, will encourage sepsis, so it should be removed. Aspiration of tense intact blisters is usually advisable. In all cases the affected part should be cleansed by gentle wash-

with soap and water, or a bland antiseptic such as 8% dettol or 1% cetavlon. If the latter is used the part should be washed with normal saline before any dressing is applied. This should be followed by the application of sterile oily dressings, such as tulle gras, vaselined gauze, paraffin, cod-liver oil, arachis oil, etc. Amyl salicylate is a very comfortable dressing, but cannot be used on the face or genitalia, or when the blisters are broken. However, it is of considerable value in reducing oedema in the first four days of treatment. Sterile sulphanilamide 3 to 5%, incorporated in the dressings, or powdered on to the affected area before the dressing is applied, will help to combat subsequent infection in areas where it is likely to develop. It should not, however, be used as a prophylactic routine over large areas, as the danger of absorption subsequently increasing the agranulocytic changes is always present. The lesions are likely to increase and the exudate from them is considerable during the first few days, so care must always be taken to see that the dressings are adequate in size and thickness and that they are held in position by bandages. Reasonable pressure helps to immobilize the part and so controls the exudate. Sticking-plaster should be studiously avoided. Dressings should be changed as seldom as is compatible with the patient's comfort.

Subsequent treatment will depend on the progress, but it should follow the lines which would be adopted with lesions of a similar appearance due to other causes, such as thermal burns and septic conditions of the skin. The value of covering the raw granulating area with perforated oiled silk, cut to the right size and held in position by a layer of zinc ointment, applied to the normal surrounding skin, is considerable. It is comfortable, the exudate can escape easily, and dressings can be changed without damage to the new granulations, as the oiled silk can be left *in situ* for many days without disturbance. It may be necessary to resort to a skin graft in the third-degree cases in which large areas are involved; but this, of course, will be impossible until the slough has separated and the sepsis has been controlled.

Prognosis

Eyes.—In the majority of cases affected by mustard gas the prognosis is good if the initial treatment has been prompt. The possibility of a functional photophobia must always be kept in mind. However, before this diagnosis is made observation by an ophthalmologist with a slit-lamp is necessary.

Respiratory and Alimentary Tracts.—In the milder cases recovery is usually complete, without residual damage, but it may take a considerable time. Lung complications are the most common cause of death. The possibility of residual fibrosis of lung and bronchiectasis must not be overlooked.

Skin.—As with thermal burns, in those cases in which the damage is either of the first or second degree—that is, erythema or erythema plus blistering—healing takes place in 14 to 21 days and complications are not common. However, in cases which progress to the third degree and in which loss of the whole true skin occurs, sepsis is a frequent complication and many weeks may elapse before healing takes place. Fortunately, most vapour burns do not go beyond the second degree, and so contractures and scarring are rare; however, the possibility of their development must be borne in mind in cases which become infected or are of the third degree. Pigmentation will almost invariably be present, but usually fades in a matter of months. Severe or repeated burns leave the skin very prone to staphylococcal infection. Prolonged exposure, either to small amounts of vapour or to repeated small burns, tends to produce a condition of hypersensitivity.

Systemic Effects.—In severe cases the systemic effects may produce fatal results as they are difficult to deal with. However, patients are more liable to die from lung complications than from agranulocytosis.

LEWISITE

Prophylaxis

Although many of the principles mentioned for prophylactic treatment are common to both mustard gas and lewisite, it is important to keep a few special points in mind with the latter.

Eyes.—Owing to intense pain and spasm of the eyelids after liquid lewisite has entered the eyes, removal by washing is extremely difficult and almost useless. Recently B.A.L. ointment, which is a specific for arsenical vesicants and of great value in the treatment of the eyes, has been developed. The instructions for applying B.A.L. ointment to affected eyes are as follows:

Place ointment upon the index finger and rub firmly between the eyelids. Pull down lower lid and insert more ointment. Close lids and rub firmly. An excess should be smeared over the lids, and the process repeated at the end of one hour.

The pain attending lewisite contamination of the eye is relieved by the application of the ointment. If B.A.L. ointment is applied within two minutes of the time of contamination complete cure may be expected; complete cure may still result if it is applied within five minutes. The amount of final damage increases with further

delay, so that if it is used after 30 minutes most eyes will eventually become sightless; beneficial effects, however, may be observed in some cases if treatment is given as late as one hour. No beneficial effects on eyes contaminated with mustard gas can be expected from the use of B.A.L. B.A.L. ointment should not be used unless one is sure that lewisite or other liquid arsenical vesicant has entered the eyes, as it produces marked blepharospasm, which may last for an hour or more. When attempting to separate mustard gas and lewisite cases it is well to remember that lewisite produces immediate and severe eye effects, whereas with mustard gas there is a delay of several hours.

Skin.—Lewisite lesions of the skin, as will be shown later, become obvious in about half an hour after they are sustained. Bleach and anti-gas ointments are not quite so efficacious with lewisite as they are with mustard gas, the danger of rapid absorption and systemic effects being greater. These can be countered by bathing the affected part with 20 vols hydrogen peroxide and afterwards leaving a compress of this liquid over the affected area. B.A.L. ointment will prevent vesication and systemic effects if applied within a few minutes and will mitigate the severity of the effects even if applied so late as one hour after contamination.

B.A.L. ointment will be held centrally under the E.M.S., and will not be issued at present.

Diagnosis

Eyes.—If liquid lewisite enters the eye immediate and intense pain and severe blepharospasm will occur, a corneal haze developing at once. Lewisite vapour produces an immediate but less painful reaction.

Alimentary Tract.—Effects will be similar to those of mustard gas, but will occur earlier.

Respiratory Tract.—The irritant effect of the vapour is severe and comes on in a few minutes.

Skin.—Tingling usually occurs soon after liquid lewisite reaches the bare skin. Subsequently the blisters which develop will be localized and tense, without surrounding erythema.

Systemic Effects.—If a large dose of liquid lewisite is allowed to remain untreated on the bare skin death may occur from acute arsenical poisoning. Lewisite, in addition to the marked effect produced on the liver and other internal organs, appears to have a selective action on the common bile duct and gall-bladder, with resulting haemorrhagic ulceration. Unlike the effect of mustard gas, the bone marrow in fatal cases is not found to be pale and agranulocytosis has not been recorded.

Treatment

The value of B.A.L. ointment has already been mentioned in prophylaxis. Subsequent treatment should be on the same lines as for mustard gas, particular attention being paid to the possible systemic effects. As with mustard gas, it has been definitely established that the exudate from lewisite blisters is innocuous.

Prognosis

This is similar to that outlined under the heading of mustard gas, except that special mention should be made regarding injury to eyes. With lewisite injury to the eyes, unless B.A.L. ointment is rapidly available, the prognosis is bad.

SUMMARY

Protection.—(1) Avoid splash by remaining under cover. (2) Protect face, eyes, and lungs by gas-mask whenever gas can be detected by smell. The sense of smell rapidly becomes fatigued. (3) If contaminated by liquid remove the outer clothing at once. If it has been worn in a gaseous atmosphere remove it at the earliest possible opportunity. (4) Treat liquid contamination of the skin by mechanical removal, anti-gas ointment, or bleach cream if available, followed by washing if possible. Washing with soap and water alone may spread contamination. (5) If liquid enters the eye and no immediate painful reaction occurs mustard gas may be assumed; it must be removed at once by profuse irrigation. If an immediate reaction and pain and blepharospasm occur, arsenicals should be assumed and B.A.L. ointment should be applied. (6) Anti-gas ointments Nos. 1 and 2 and bleach cream are all skin irritants, and must be washed off if they are used. (Note: Anti-gas ointment No. 1 is obsolete.) (7) If there is no visible liquid on the skin it can be assumed that the patient is safe to handle. (8) The antidote for lewisite on the skin is hydrogen peroxide 20 vols.

Treatment of Eyes.—(1) Constant irrigation is detrimental. (2) Bandaging must be avoided. (3) Protection from the light by cardboard eye-shades is permissible. (4) Do not use local analgesics or antiseptics. (5) In bad cases a mydriatic should be used until pupillary dilatation is achieved. (6) Sticking of the lids can be avoided by smearing them with paraffin. (7) Sulphacetamide (albicid) drops relieve discomfort and combat subsequent infection. (8) B.A.L. ointment, if applied early, is a specific for eye and skin damage due to arsenical vesicants.

Treatment of Skin.—(1) Do not use any prophylactic treatment when the skin is showing actual signs of damage, unless lewisite is suspected by early skin changes. The value of B.A.L. at this stage is considerable. (2) Remove hair from affected area with clippers. (3) Clean the part with bland antiseptic. (4) Leave blisters intact whenever possible. (5) Remove redundant skin only if it is unavoidable. (6) Apply a sterile oily dressing. (7) Sulphonamides can be used to counteract infection if no systemic effects are present. (8) Any form of coagulant treatment is contraindicated. (9) Never change a dressing unless it is absolutely necessary. (10) After the first few days each case must be treated on its merits, keeping in mind the actual clinical manifestations rather than their origin. (11) The exudate from mustard gas and lewisite lesions is innocuous. (12) In serious cases it is essential to watch the condition of the blood so that appropriate action can be taken to counteract any adverse effects.

A list of those appointed by the E.M.S. to assist in the treatment of gas casualties will be found in the E.M.S. Instruction No. 283 (revised June 1, 1943).

I should like to express my gratitude for the help received from Dr. Stopford Taylor on the treatment of skin, Mr. T. J. Phillips on the treatment of eyes, and Brig. Pollitt on the treatment of burns. The staffs of the Ministry of Home Security, the Emergency Medical Services, the Passive Air Defence, and the Ministry of Supply have also given me much valuable information.

RUPTURE IN A SUPPOSED LOWER SEGMENT CAESAREAN SECTION SCAR

by

D. W. JAMES, M.B., B.S.

Owing to the increasing popularity of the lower segment operation, rupture of a Caesarean scar during a subsequent natural labour is becoming a rare accident. The following case is reported in order to show that the possibility of rupture should always be considered, even when the scar is believed to be in the lower segment.

Case History

Previous Operation.—The patient was a para-1 aged 35. No accurate notes of the former operation could be obtained. It was performed at an R.A.F. hospital, and personal contact with the medical officer who performed it was impossible, as he is now abroad. The abdominal scar extended from the umbilicus to the suprapubic region in the midline. So far as could be ascertained from the hospital, a "lower segment" Caesarean section had been performed on Feb. 18, 1939, for an extended breech presentation with a small pelvis. Version having failed, the patient was delivered before the onset of labour of a living child weighing 5 lb. 4 oz., and she made a good recovery.

Second Pregnancy.—This was uneventful throughout. She had been warned early in the pregnancy, in view of her previous operation, that it would be necessary for her to be delivered in hospital according to the usual custom. During the last few weeks of her pregnancy she was kept under close observation for signs of overstretching of the uterine scar, but nothing abnormal was apparent. At 38 weeks the vertex was presenting and the head was well engaged in the pelvis with the occiput anterior. Although the promontory could be felt at a little over 4 inches, disproportion appeared to be negligible. At her last attendance at the antenatal clinic the uterine scar again appeared to be perfectly satisfactory, and it was decided that a natural labour should take place under observation in hospital.

Onset and Progress of Labour.—Labour began naturally on the expected date, and the patient was admitted to the Maternity Unit of the North Herts and South Beds Hospital with vague labour pains at 7 a.m., on Feb. 11, 1943. The membranes were intact, the head was engaged in the L.O.A. position, and there was nothing to indicate that the course of labour would be abnormal. At 11.30 a.m. on the same day it was noticed that the lower part of the abdominal scar was a little prominent in the suprapubic region. The appearance suggested, in fact, that the bladder was not completely empty. A catheter was passed, and 2 oz. of urine withdrawn without alteration in the abdominal contour. The maternal pulse was 80 at this time. The limbs were easily felt under the scar, but there was no local pain or tenderness. The cervix admitted one finger and contractions were weak. She remained perfectly comfortable, with occasional weak contractions, until 4 p.m., when she suddenly vomited and complained of sharp pains in the lower abdomen. Her general condition was good, but her pulse rose to 100. The lower part of the abdominal scar was plainly larger than before, and on palpation gave the impression that the limbs were just under the skin. There was now some local pain and tenderness, and with each

contraction the lower part of the scar bulged in the suprapubic region. Impending rupture of the uterine scar was diagnosed, and it was decided to perform an immediate laparotomy. Half an hour later she began to complain of continuous pain, and the bulge had extended along the entire length of the abdominal scar. By the time the patient was in the operating theatre, at 5 p.m., foetal parts were easily felt under the skin, and it was evident that rupture had occurred.

Operation.—Anaesthesia was induced with gas and oxygen and maintained with the addition of trilene. On opening the abdominal cavity through a midline incision free blood and liquor were encountered. The arm and shoulder of the foetus presented through an irregular laceration, which appeared to extend from below on the right side of the lower uterine segment to a point higher up on the left side of the body of the uterus. A leg was seized and the child delivered through the rupture by the breech. After a short period of asphyxia it recovered and cried almost at once. After separation and removal of the placenta and membranes it could be seen that the rupture extended well up into the body of the uterus close to the origin of the round ligament on the left side. The edges of the wound were badly lacerated, friable, and infiltrated with blood-clot. There was also considerable haemorrhage between the layers of the broad ligament on the left side. A subtotal hysterectomy, with conservation of the ovaries, was therefore performed, and the abdomen closed. Immediately after the operation the patient's condition was fairly good. Her pulse was 120. A blood transfusion had been started when it was decided to perform hysterectomy and 500 c.cm. was given rapidly, followed by a further 500 c.cm. by slow drip on her return to the ward. Three hours after the operation her pulse was 96 and her general condition much improved. The puerperium was apyrexial; she was allowed up on the 14th day, and she returned home after three weeks, breast-feeding the baby.

Pathological Report upon the Uterus.—I am indebted to Dr. W. Woods, of the Institute of Pathology, London Hospital, for a description of the specimen, as well as of microscopic sections through the old Caesarean section scar. "The specimen is the upper part of a parturient uterus. It measures 13 cm. long in the posterior wall and from 9 to 12 cm. long in the anterior wall, and 11 by 7 cm. across the fundus. The appendages are absent. The serosa is smooth. The lower edge of the posterior wall is the cut edge of hysterectomy. In the anterior wall the lower edge of the specimen is the rupture. Immediately above the rupture, and partly in it, the old Caesarean scar is faintly seen as a contracted area of myometrium with a few tags of omentum adherent to it. The rupture and scar pass obliquely across the anterior wall from the right side at a point 9 cm. below the uterine attachment of the right ovarian ligament to end in the left side at a point 1.5 cm. below the left ovarian ligament. The scar is therefore in the body of the uterus and not in the lower segment. In the microscopic sections made across the rupture evidence of the scar is seen as an area of fibrosis, with contraction, in the myometrium. There is continuity of muscle fibres through the scar."

Discussion

Commenting upon the few cases of rupture of a lower segment scar that have been reported, Marshall states: "There is more than a suspicion that in several of these cases the incision was not wholly confined to the lower segment, and that it was the corporeal part which subsequently ruptured." Although he was referring chiefly to the vertical incision, this criticism might well be applied to the case reported above. In fact, it is clearly shown by the pathological report that the incision was placed entirely in the body of the uterus, although it was evidently intended to be in the lower segment.

The oblique direction is not easily explained. Whether the incision was intended to be vertical, or whether this was the result of an asymmetrical curve upwards in a transverse incision it is impossible to say. The patient was not in labour at the first operation, and it is possible that the development of the lower segment was defective or that it was difficult to define. Nevertheless it emphasizes once more the importance of a really low transverse incision.

Certain conclusions may be drawn from this case with regard to previous Caesarean operations in general: (1) That full notes of a previous Caesarean operation should always be obtained if possible. (2) That the abdominal scar is not necessarily a true indication of the nature of the uterine scar. (3) That great vigilance is necessary in all cases previously delivered by Caesarean section and subsequently allowed to deliver by natural labour, which must take place in a hospital. (4) That definite signs of overstretching of the scar usually precede the

actual rupture, and that rupture may occur with only weak contractions. (5) That the prognosis depends upon the time elapsing between rupture and laparotomy.

Early diagnosis of impending rupture should reduce the mortality to a minimum. In the case reported only a few minutes elapsed between rupture and the delivery of the child. A little earlier and the uterus might have been saved; a little later and two lives might have been lost.

I wish to thank Mr. Eardley Holland for his valuable criticism and suggestions, and for his permission to publish this case.

MEIGS'S SYNDROME

HYDROTHORAX AND ASCITES IN ASSOCIATION WITH FIBROMA OF THE OVARY

BY

AUSTIN G. CLAY, M.D. *Aberd.*

Senior Resident Physician, Aberdeen City Hospital

ROBERT N. JOHNSTON, M.B., Ch.B. *Aberd.*

Resident Medical Officer, Aberdeen City Hospital

AND

LEOPOLD SAMSON, M.D. *Hamburg*

Gynaecological Registrar, Aberdeen Royal Infirmary

Pleural effusion and ascites may be found in association with cardiac, renal, or hepatic disease, and in the absence of any such clearly defined clinical syndrome are commonly attributed to carcinomatosis or tuberculosis. The association of simple fibroma of the ovary with ascites is well known, free fluid sufficient to be recognizable clinically being found in 75% of cases. Pleural effusion in association with ascites and fibroma of the ovary is a rare condition. Only 28 cases have been reported in the literature, 27 of these being from America and one from Great Britain. It is our purpose to describe two such cases which have recently occurred in Aberdeen, as we believe that others may go unrecognized and, since ascites and hydrothorax immediately suggest an inoperable growth, some patients may have died unnecessarily. This is suggested by the fact that patients who were very seriously ill have made excellent recoveries after operation.

Previous Cases

The first case was reported by Cullingworth in 1879, and the patient died without operation. The condition was first described in 1892 by Lawson Tait, who advocated exploring the abdomen in patients with abdominal and chest fluid, for he considered that this combination did not always mean cancer. There was no further reference until 1923, when Hoon of the Mayo Clinic reported two cases. Meigs (1934) referred to 3 cases, reported 4 in collaboration with Cass in 1937, and in 1939 summarized 15 more cases. Later, in 1940, this total was increased to 18, while in 1943 further cases were described by Meigs *et al.*, bringing the total of authentic cases described in America to 27. Rhoads and Terrell first used the term "Meigs' syndrome" when reporting a case in 1937. In Dec., 1943, Gild described one case in England.

Recorded Signs and Symptoms

In the majority of cases the history was that of dyspnoea, loss in weight, fatigue, cough, and pain in the chest, while on physical examination a massive pleural effusion was found in association with a greater or less quantity of abdominal fluid together with a pelvic tumour. The tumour may be a large and easily palpable mass associated with a clinically undetectable quantity of abdominal fluid or, alternatively, may be no larger than a walnut, only discoverable in the presence of considerable ascites, at operation. In all cases the pleural effusion has been of a massive nature causing collapse of the lung on the affected side and displacement of the mediastinum. The condition may occur at any age, the oldest patient being 73, and it has even been found complicating pregnancy. The right side of the chest is more often and usually more extensively affected than the left. There is no recurrence of the effusions after removal of the tumour, and indeed spontaneous resolution

of the chest occurs within a few weeks. This is in marked contrast to what happens before operation, when, following the removal of large quantities of fluid, the chest fills up again in a matter of a few days, or in some cases within 24 hours. In some instances there is so little fluid in the abdominal cavity that paracentesis may fail to locate it, but some will always be found at operation.

Case Histories

Case 1.—An unmarried woman aged 59 was admitted to the gynaecological ward of the Aberdeen Royal Infirmary with a complaint of breathlessness for the past year. She had noticed a lump in her abdomen for about the same period. The last menstrual period occurred ten years previously. The patient was emaciated and slightly orthopnoeic. There was a right pleural effusion, producing a mediastinal shift to the left. The abdomen was distended by a large irregular cystic swelling arising from the pelvis and reaching above the umbilicus. Vaginal examination revealed a small uterus distinct from the tumour. X-ray examination disclosed a large chronic effusion almost completely filling the right chest. The sputum showed no evidence of tubercle bacilli. The blood sedimentation rate was 15 mm in the first hour. Almost five pints of straw-coloured fluid was removed from the right pleural cavity. Bacteriological and pathological examination of this fluid failed to show evidence either of tuberculosis or of malignant disease. Laparotomy by Prof. Baird two weeks after admission demonstrated a big unilocular cyst about 8 in. in diameter attached to the left broad ligament. There was a small quantity of fluid in the peritoneal cavity. The cyst was removed and the abdomen closed. Histologically the tumour was shown to be a cellular ovarian fibroma with marked cystic degeneration but no evidence of malignancy. Recovery was rapid and no further breathlessness has been noted. Her general condition improved steadily and the emaciation quickly disappeared. A radiograph of the chest three months after operation showed the lungs to be normal.

Case 2.—A married woman aged 47 who had one child, now aged 25, was admitted to Aberdeen City Hospital as a case of pulmonary tuberculosis. Her complaint was breathlessness for the past five months. The menstrual history was normal. She was a thin, rather wasted woman—breathless while lying in bed. There was a large pleural effusion on the right side with a slight mediastinal shift, and on abdominal palpation a large mass was felt rising out of the pelvis to the level of the umbilicus, but no free fluid could be detected. On vaginal examination a hard mass was very easily felt in the right fornix. X-ray examination of the chest showed a large pleural effusion on the right side. The left lung was normal. No tubercle bacilli were found in the sputum by direct film or on animal inoculation. The blood sedimentation rate was 10 mm. in the first hour. The right pleural cavity was aspirated and the fluid replaced by air. The fluid was clear, and histological examination of centrifuged deposit showed no evidence of malignant disease, while animal inoculation of two specimens failed to reveal the presence of tubercle bacilli. Subsequent x-ray examination disclosed a right hydropneumothorax with complete collapse of the right lung. In all, 35 pints of fluid were removed from the right pleural cavity. Paracentesis of the abdomen failed to elicit fluid. An exploratory laparotomy was performed by Prof. Baird two months after admission. There was less than a pint of fluid in the peritoneal cavity, and a large white lobulated tumour (7 by 6 in.) was found attached by a pedicle to the right broad ligament posteriorly. The left ovary was normal. The tumour was removed, and proved to be a typical ovarian fibroma with no evidence of malignancy. Post-operative convalescence was uneventful. Further radiographs of the chest showed rapid absorption of the right pleural effusion, and ten weeks after operation only a trace of fluid was detectable. The right lung had expanded, and the patient's general condition had greatly improved.

Aetiology

No satisfactory explanation exists to account for the phenomenon. The suggestions which have been offered are: (1) lack of drainage of the right chest by the azygos vein; (2) repeated minor trauma to the peritoneum by the fibroma, causing a histamine toxicosis or anaphylactic shock plus accumulations of peritoneal and pleural transudate; (3) congenital communication between the abdomen and the chest—the so-called pleuro-peritoneal canal.

None of these explanations have been satisfactorily proved. Meigs *et al.* introduced a quantity of air into the pleural cavity, the patient then being tilted into the Trendelenburg position and x-rayed without any evidence of air being forced into the abdomen. The reverse procedure, whereby a considerable quantity of air was pumped into the abdomen to the point of discomfort and dyspnoea in an effort to demonstrate any passage-way for air from the abdomen to the thorax, has also

An operation was performed without delay through a left pa median incision. The stomach at once presented itself, very te and like a distended rubber balloon. By passing the hand ro the left-hand surface of the stomach it was possible to reach the edge of the diaphragmatic aperture, and by manipulation the in thoracic portion of the stomach was successfully withdrawn. moment this was done the whole stomach turned over from ri left. In its distended condition it was approximately 18 to 2 long and 8 or 9 in. in diameter. It was clear that there was no obstruction at the pylorus. By turning the stomach over to right it was possible to see the opening in the diaphragm, which to the left of the oesophageal opening, and admitted two fi easily. The opening was occluded by a stout double catgut sut and the abdomen was closed. On April 5 there were signs of left-sided basal pneumonia, which cleared up in a few days, the patient was discharged on April 19 with no symptoms.

She was x-rayed again on June 9. This showed a rather large stomach, but no sign of any recurrence of the hernia. She has remained entirely free from gastric symptoms since her discharge from the hospital, and six months after the operation had had no further trouble.

COMMENT

The case is interesting on account of the condition found at operation, where the stomach was twisted and enormously distended, and by the rapid recovery of the gastric functions in spite of the excessive stretching of the muscular and mucous wall of the stomach. How the torsion had occurred must be a matter of pure conjecture, but the impression at the time of the operation was that the pyloric end of the stomach had been dragged or twisted to the left side into the hernial orifice. The original radiograph, taken in 1939, showed the ordinary condition of herniation of the fundus.

London, W.1.

HAROLD GARDINER, M.S., F.R.C.S.

Varicella and Herpes Zoster in the Same Patient

It is very unusual to encounter the characteristic eruptions of chickenpox and herpes in the same patient, and I am not aware of any record of a similar case in a child. The significant features appear to be the allergic history and the somewhat diffuse distribution of the herpetic eruption apparently involving the anterior divisions of numerous nerve roots.

The patient, a boy aged 5½ years, is an only child, sensitive, highly strung, precocious, allergic to pollens and mixed inhalants group. The father has a history of allergy in his childhood. The boy developed typical chickenpox on Dec. 29, 1943. The attack was mild, being afebrile after two days. On Jan. 22, 1944, there was an eruption of herpetic vesicles on the right side extending from the clavicle and deltoid area over the chest and abdomen to the upper half of the right thigh. The eruption was limited by the midline in front and by the mid-axillary line. Apart from the discomfort of the eruption, there were no unusual symptoms until Jan. 27, when the temperature rose to 102° F. and the next day to 104°. It gradually subsided, and was normal by Feb. 3.

On Feb. 2 he had some malaise accompanied by loss of appetite, dirty tongue, enlarged and tender liver, and pale stools; there was no obvious jaundice to the naked eye, but bile was present in the urine. This lasted two days and rapidly cleared up. On Feb. 14 he had an attack of typical asthma.

I am indebted to Dr. S. R. Foster, the family physician, for his interest and co-operation, and for some of the additional clinical notes.

Belfast.

F. M. B. ALLEN, M.D., F.R.C.P.

Concurrent Herpes Zoster and Varicella

The following case seems worthy of record if only for its extreme rarity. The relation between herpes zoster and varicella was first noticed by J. Van Bokay in 1892. Since then the relationship has attracted much attention, and most practitioners are agreed as to the increased incidence of herpes zoster in epidemics of varicella. Up to 1930 Netter of Paris had been able to collect only 20 cases of concurrent herpes zoster and varicella, and some eminent authorities were inclined to attribute the concurrence to mere coincidence. Cranston Low has advanced the theory that both diseases are due to the same virus, in one case affecting the nervous system and in the other being blood-borne. The case described below seems to favour this theory.

A man aged 63 came to see me on March 9, 1944, complaining of pain in the left hypogastrium with a generalized rash. On examination I found typical symptoms of varicella as to both lesion and distribution. In addition the painful area showed typical herpes zoster. He stated that he had felt "off colour" on March 5. By evening he had pain in the left side and found some "blisters," and at the same time felt an irritation of the face and scalp. On the morning of the 6th he was covered with a well-developed rash. Both rashes have since run a normal course. The patient is a chronic bronchitic who has not worked for months, and he shares a house with another elderly man. There is an epidemic of varicella at the time of writing (March 29).

Additional points of interest are: (1) the coincident appearance of the rashes; (2) the age of the patient.

Warrington, Lancs.

J. J. MANNING, M.B.

The Professional Advisory Committee of the U.S. Office of Vocational Rehabilitation held its first meeting in Washington on March 3. The committee, made up of 20 specialists in medical and allied fields, was appointed to provide professional guidance in mapping the new State-Federal programme for medical and surgical care under the Barden-LaFollette Act. In opening the meeting Mr. Paul V. McNutt stressed the Federal Security Agency's desire to aid the States in providing physical restoration services which will conform to the high professional standards recognized by the national and State medical associations and by the hospital associations.

Reviews

GENERAL AND SPECIAL BIOCHEMISTRY

Annual Review of Biochemistry. Edited by James Murray Luck, Associate Editor, James H. C. Smith. Volume XII. (Pp. 704. 31s. 6d.) California: Stanford University P.O., Annual Reviews, Inc.; London: H. K. Lewis and Co.

Vitamins and Hormones. Edited by Robert S. Harris and Kenneth V. Thimann. With a foreword by E. V. McCollum. Volume I. (Pp. 452. 56.50.) New York: Academic Press, Inc.

The twelfth volume of these annual reviews is, like earlier ones, a co-operative effort of American and British experts—three chapters having been contributed by writers in this country and the other twenty-one by United States scientists. The standard of previous volumes is admirably maintained. The individual articles are detailed, highly technical, authoritative surveys generally covering a period of four or five years, which is about the time allowed by the editors before a subject is picked up again. Readers of this *Journal* will find much here that bears indirectly but fundamentally on medical practice, if sometimes possibly only on future practice; but they will also be able to read with a more direct interest chapters on nutrition in 1941 and 1942 (C. S. Lanford and H. C. Sherman), on synthetic drugs (T. C. Daniels), on the metabolism of proteins and amino-acids (H. B. Brock and J. W. Dubnoff), of fat (G. O. Burr and R. H. Barnes), and of carbohydrate (H. J. Deuel jun.), as well as accounts of the water-soluble and the fat-soluble vitamins (R. J. Williams and K. Hickman respectively). Of practical interest, in a rather different way, are chapters on the electron microscope in biology (L. Marton) and on microchemistry (A. A. Benedetti-Pichler), while for those with a taste for the more fundamental and theoretical sides of biochemistry H. A. Krebs has written on carbon dioxide assimilation in heterotrophic organisms, E. S. Johnston and J. E. Myers on photosynthesis, and F. Lipmann on biological oxidations and reductions. Other chapters are concerned with the primarily chemical aspects of steroids (H. Sobotta and E. Block), of proteins and amino-acids (L. F. Hewitt, R. A. Kekwick, and A. S. McFarlane), of sulphur compounds (J. C. Andrews), of carbohydrates (H. S. Isbell), of the lipins (S. J. Thannhauser and G. Schmidt), of hormones (H. Fraenkel-Conrat), of animal pigments (C. Rimington), and of viruses (C. L. Hoagland). Finally, to round off the picture, astonishingly complete for wartime, there are reviews of mineral nutrition (L. A. Maynard and J. K. Loosli) and of mineral nutrition of plants (D. I. Arnon). The book is as indispensable to research workers and teachers in or near the field of biochemistry as have been its predecessors in this excellent series.

Prof. McCollum in his foreword refers to *Vitamins and Hormones* as a new publication, as indeed he had to do when introducing a "Volume I." But those who know and possibly possess the two issues of *Ergebnisse der Vitamin- und Hormonforschung*, published by the Akademische Verlagsgesellschaft of Leipzig in 1938 and 1939, may reasonably regard this survey as more of a phoenix than a new creation. However that may be, the United States compares in every way favourably with its Swiss-German predecessor. Nothing, for example, could be better done than Prof. C. H. Best and Dr. C. C. Lucas's review on "Choline: Chemistry and Significance as a Dietary Factor"; in 60 pages, closely packed with information and discussion, they open up the allied problems of fatty livers and transmethylation, nor do they neglect to indicate emphatically where judgment must be suspended and more experiments made. Of somewhat slighter calibre, though of no less authority, is H. H. Mitchell's review of the relationships between vitamins and amino-acids. Wald's discussion of the part that carotenoids (including vitamin A) play in the photoreceptor system is perhaps the most controversial in the book; it comes from an expert with whom other experts in the field are not in whole-hearted agreement. R. J. Williams speculates interestingly on the distribution of vitamins in various tissues and organs, while Richard P. Hall discusses the more circumscribed subject of growth factors for protozoa. Norman Jolliffe and Rita M. Most contribute a discussion on the appraisal of nutritional states, practical and topical. The review of the physiology of anti-pernicious-anaemic

material by George R. Minot and Maurice B. Strauss is clearly the last word on the subject at the time of its writing. The surveys of the intermediate metabolism of the sex hormones by Gregory Pincus and William H. Pearlman and on the adrenal cortical hormone by T. Reichstein and C. W. Shoppee are of the same calibre, the latter being, apparently, the only contribution to this volume by authors not resident in North America. There is reason to believe that the editors will have arranged in later volumes for the collaboration of authors in Great Britain, for whom this first volume has set an almost terrifyingly high standard.

THE HOSPITAL ALMONER

Social Service in a General Hospital. By Dorothy Manchée. (Pp. 164. 6s.) London: Baillière, Tindall and Cox. 1944.

The more the science and art of medicine advances the more does it become apparent that it is closely linked with every other branch of knowledge. The patient is not an individual in a vacuum; he can only be fully understood in relationship with his environment, his friends and family, his economic status, and his housing facilities. In this little book Miss Manchée shows not only how important these factors are, in both diagnosis and treatment of almost every patient who comes to a doctor, but also how a well-organized almoner's department in a hospital can help the physicians and surgeons in their day-to-day work. After introductory chapters on the social services, the various departments and services of a large hospital are considered from the almoner's point of view. This is followed by a very brief discussion of the clinical characteristics of various types of patient, such as the cancer case, the diabetic, the orthopaedic patient, and so on. These notes are simple, and while it might be easy to criticize some of them they are sufficiently accurate and adequate for the aspiring almoner. Then the duties of the social worker in relation to these various types are discussed. Very properly the importance of such work in relation to the V.D. department is stressed, and it is to be hoped that all those concerned will take note of this. It is easy and pleasant to undertake social work on behalf of the cripple child, but not so easy and pleasant to do this for the young woman who has fallen by the way; yet the latter needs it quite as much as the former, if not more. One most important point is stressed—that the almoner is a social worker and not a fee-snatching agency; she should be free to do her proper work, which includes the collection of money to help her patient, and there is an excellent chapter on the sources to which she may look for this assistance. The last few chapters are devoted to the instruction of the student and a general discussion of the functions of the department. A useful bibliography is appended.

While some members of hospital staffs are keen on the almoner and make good use of her, it may be suspected that the majority do not use her half enough, and everyone would well advised to read this interesting and well-written book.

MERCER'S ORTHOPAEDIC SURGERY

Orthopaedic Surgery. By Walter Mercer, M.B., Ch.B., F.R.C.S. Ed. Third edition. With foreword by Sir John Fraser, Bt., K.C.V.O. (Pp. 947; Illustrated. 45s.) London: Edward Arnold.

Mercer's *Orthopaedic Surgery* has made a place for itself, as the appearance of a third edition indicates. The new volume is a few pages longer than its predecessor, though the quality of the paper and to some extent the reproduction of illustrations and the reduction of the valuable bibliography reflect the stringency of wartime publication. On the whole the layout is clear and the description lucid, so that reading is not laborious and items of interest can be easily found.

Mr. Mercer still seems unable to decide whether the syndromes between the vertebral bodies are joints or not, for, while stating that they are "not joints in the true sense of the word," he describes posterior spinal fusions as "extra-articular arthrodeses in the truest sense of the word." They are, in fact, joints, and perhaps a better concept of surgical tuberculosis would be gained by the student if tuberculosis of the spine were considered under tuberculosis of joints. Juxta-articular lesions are, indeed, the usual sites of onset, whether in hip or spine, but as a rule joint involvement soon follows in both.

A few minor points surprise us, such as that rupture of the long head of the biceps brachii is so rare that it is associated

with old fractures of the humeral neck rather than with arthritis, and that the treatment is operative repair. Again, the use of a knee cage in the treatment of torn cartilage and its ability to control rotatory movement at the knee seem open to question. Rather too much emphasis and room are accorded to operative details, and too little to the important features of treatment which precede and follow operations and which occupy most of the orthopaedic surgeon's time and interest.

The book has been brought up to date and will prove of particular value to those working for higher surgical qualifications or embarking on a surgical career. In spite of the points which invite criticism here or there, it will continue to hold an important place in the literature of orthopaedic surgery.

Notes on Books

The Textbook of Surgical Treatment, edited by Prof. C. F. W. ILLINGWORTH of Glasgow and written by himself and eighteen other Scottish surgeons, appeared first at the beginning of 1943. We welcomed it as a sound and modern work likely to run into future editions. That opinion is supported by the publication within 15 months of a second edition (Edinburgh: E. and S. Livingstone; 30s.). The most notable change is in the chapter on treatment of burns, which has been rewritten by Mr. Thomas Gibson from his experience in the Burns Unit of the Glasgow Royal Infirmary.

The fourth edition of *Medical Bacteriology*, by L. E. H. WHITBY (J. and A. Churchill; 14s.), contains a new chapter on chemotherapy in the extensive section on applied bacteriology, which includes as before instructions for the laboratory diagnosis of infections listed alphabetically. Since in a total of 328 pages the book deals also with protozoology, helminthology, and mycoses, the systematic description of pathogenic bacteria has to be compressed into a perhaps unduly small space, and the intelligent reader will do well to heed the advice in the preface to consult larger textbooks for further enlightenment on some aspects of the subject.

The third edition of the valuable little textbook *Midwifery for Nurses*, by ALECK W. BOURNE, has now appeared (J. and A. Churchill; 7s. 6d.). It is full of sound common-sense teaching presented in a very readable form. Stress is given to such essentials as health of body and mind in pregnancy, delayed labour, ante-partum and post-partum haemorrhage, and sepsis. It can be warmly commended to midwives.

Aids to Tropical Nursing, by DOROTHY E. COCKER, sister tutor, Presidency General Hospital, Calcutta, is published at 4s. by Baillière, Tindall and Cox. This small book is one of the Nurses' Aids Series designed to provide in condensed and easily absorbable form information on tropical diseases from the nursing aspect, and this object has been admirably fulfilled. Beginning with chapters on fitness in the Tropics and the essentials of deficiency diseases, it proceeds to consider each main infection in turn. The information is accurate and singularly free from technical errors. It concludes with a summary of communicable tropical diseases, an adequate glossary, and an index. The figures are mostly temperature charts, but include simple illustrations of malaria parasites and methods of preparing blood films. There is one obvious misprint: the initials of Dr. Napier, who contributes a foreword, are L. E., not L. N. as stated.

Doctor of Tanganyika, by Dr. PAUL WHITE, is published by George M. Dash of Sydney, N.S.W., price 6s. This small book tells of the life and work in British Central Africa of an Australian medical missionary. Dr. Paul White is obviously self-reliant, capable, and energetic, and the possession of these qualities helped him through a vast amount of work. He built a hospital and trained native male and female assistants. The book has found great favour in Australia, where it has gone through seven editions. It depicts the life led by the primitive African tribes in Central Tanganyika Territory and the hardships these people have to undergo at the hands of witch doctors. Dr. White's story will impress on intending medical missionaries the need to become as well grounded as possible in every branch of medicine and surgery.

The greater part of *The Dental Surgeon's Handbook*, by MARTELL and MAX BRONNER (John Wright and Sons; 21s.), is devoted to extensive but somewhat disjointed notes on dental surgery arranged in alphabetical order. A second section is on materia medica, with a description of most of the drugs and proprietary substances used by the dental surgeon. The volume can only be regarded as a book of reference, and in this respect should be useful to some practitioners.

TRIOFAX

Triple Dye Jelly

'Triofax' brand Triple Dye Jelly is a stable, water-soluble preparation incorporating the triple-dye formula which has been widely advocated for the treatment of burns, particularly of the face or extremities. It produces a light flexible tan which remains in place until healing is complete. The combined dyes form an effective antiseptic barrier against infection and sepsis. 'Triofax' is useful in

the treatment of skin disorders such as cutaneous ulcers, impetigo, impetiginous dermatitis, seborrhoeic dermatitis and intertrigo.

TUBES OF 1 OZ. AND 4 OZ.

TRIOFAX TRIPLE DYE JELLY

1% Violet, 1 per cent; Brilliant Green, 0.1 per cent, and Eosin, 0.1 per cent.

TINEA INFECTIONS OF THE SKIN

● 'Mersagel' is a convenient product with a single clinical purpose, the treatment of the more common mycotic infections, chiefly ringworm of the foot, groin and axillae.

It consists of phenyl mercuric acetate, once again in a jelly base. Lightly rubbed into the affected parts and then covered with gauze on lint, 'Mersagel' cleans up acute infections after a few applications. 'Mersagel' can also be used prophylactically among contacts.

PRODUCT OF THE
GLAXO LABORATORIES

MERSAGEL

BRAND OF
PHENYL MERCURIC ACETATE (1 in 750)
1½ oz. and 16 oz.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434

The improved tar preparation

E.S.T.P.

BRAND

(MARTINDALE)

Ether Soluble Tar Paste

Purified, decolorised,
non-staining, aromatic
maximum tar effect

A smooth paste, easily applied. The tar component retains the essential phenolic compounds unimpaired, ensuring powerful antiseptic action. All indications for Tar Treatment are indications for "E.S.T.P." (Martindale), more especially infantile eczema; eczema generally, subacute, acute, chronic, moist and dry, with their multiform lesions; impetigo complicating occupational eczema; prurigo; pruritus; psoriasis; pityriasis circinata; lichen planus

In 2 oz. and 16 oz. jars. Sample and Literature on request.

W. MARTINDALE, Manufacturing Chemists, New Cavendish St., LONDON, W.1

REFORM OF MEDICAL EDUCATION

Few bodies in the history of British medicine can have had a greater opportunity or more responsibility than the Interdepartmental Committee appointed in March, 1942, under the chairmanship of Sir William Goodenough "to inquire into the organization of medical schools, particularly in regard to facilities for teaching and research, and to make recommendations." Progress in the science and art of medicine is inseparably connected with the facilities which our medical schools provide to attract the right men and to enable them to do their best work. The doctor's service to the community depends not only on his innate gifts but on the way in which he has been trained to think and do. And so the nature of medical education and the organization and facilities of our medical schools are some of the most potent factors in shaping the standard of medicine. At no previous time has there been an opportunity to survey the whole of medical education, in order to remedy its defects, with more certainty that something must be done. Change is inevitable; the destruction wrought by war and the people's desire for an improved health service make it so.

This eagerly awaited and now published report is a long one—312 pages, including 28 pages of summary—and it is impossible here to note more than a few of its chief points. The way is to be made easier for the student. All medical schools are to become co-educational. To increase the field from which students are selected, increased financial grants and a simplified machinery for distributing them are recommended. Students should not be selected on examination results alone. Accommodation should be provided in halls of residence for part of the undergraduate period, and for specific purposes in hospital during part of clinical training. The instrument of medical education should be a medical teaching centre catering for a student entry of 80 to 100 for the clinical years; and it should comprise a medical school which should be a faculty, college, or school of the university, a parent teaching hospital of 950 to 1,000 beds, and a group of neighbouring hospitals and clinics to provide supplementary facilities for clinical teaching. The governing bodies of medical school, parent teaching hospital, and associated teaching hospitals are to remain separate, but their work is to be co-ordinated by interchange of personnel and through common advisory machinery for selection of staff. In the main the details as to how these objects should be attained are left to the schools themselves. Important suggestions relating to certain schools are, however, made. In Scotland the three extramural schools in Glasgow and

Edinburgh, which, receiving no Government grants, compare unfavourably with the university schools, are to disappear. In London the facilities provided by the West London Hospital should lapse after some years; to harmonize with the redistribution of population, Charing Cross is advised to move to a site in Middlesex, St. George's to South London, and the London School of Medicine for Women to North London. All are to be complete schools in that preclinical as well as clinical facilities are to be provided, and all are advised to conform to the ideal size and pattern already mentioned. The proposal to provide in Oxford complete clinical facilities for a small number of undergraduates is approved, and the very important recommendation is added that this school should experiment in teaching. Cambridge is unsuitable at present for undergraduate clinical teaching; it should first develop postgraduate departments. No new medical schools are to be created. In view of the importance of the universities and medical schools to any national health service, they should be represented on such central and local councils as may be set up for administration.

The report points out that the accommodation and equipment of most medical schools and teaching hospitals fall far short of what is necessary for teaching and research, and recommends that grants be made to remedy these deficiencies. Teachers in both preclinical and clinical departments should be more numerous and better paid. A national range of salaries with upper and lower limits is suggested: for example, at pre-war values professors would receive between £1,500 and £2,500, demonstrators between £350 and £500, and whole-time physicians or surgeons between £1,000 and £2,000 a year, part-time teachers being remunerated proportionally to the time they give. The teaching staff in all preclinical departments and in pathology should be whole-time. As suitable men become available, every school should aim at securing whole-time professors of general medicine, surgery, and obstetrics and gynaecology; in the special departments it may sometimes be desirable for men to work whole-time in the teaching centre. Most senior clinical posts would remain part-time, but the junior posts would be full-time. All appointments should be made from the widest possible field of applicants, and above that of registrar by a small advisory council including outside experts and representing the hospitals concerned, the university, or school.

Recommendations concerning the curriculum resemble in broad outline, though differing in certain important details from, those made by the College of Physicians. Elementary physics, chemistry, and biology should be taught at school as part of general education, and continued at the medical school as part of the course in anatomy and physiology. The standard required for entry to a medical school should be midway between that of the principal and subsidiary subjects of the Higher Certificate. Preclinical subjects should be pruned of some detail and more closely co-ordinated with each other and with clinical studies. In the clinical period the main emphasis should be on basic principles and methods, and on the future requirements of the general practitioners. The important recommendations are made that much of the teaching of

operative surgery and gynaecology should be reserved for the postgraduate training of specialists. In the undergraduate period the chief emphasis in surgery should be on principles, and on the recognition, early treatment, and ultimate effects of conditions commonly met in general practice. The committee recognizes the difficulties raised by the growth of specialism in the teaching of general medicine and surgery, and recommends that to facilitate co-ordination the teaching centre should be organized into divisions of (1) preclinical studies, (2) pathology, (3) medicine, (4) surgery, and (5) obstetrics and gynaecology, each with academic heads. Senior teachers, whether whole-time or part-time, would have as now the unfettered control of the management of their patients. The importance of social medicine, psychiatry, and child health is stressed, and the desirability of students' residence during part of their training pointed out. The undergraduate course should last four and a half years, of which the first two should be preclinical. It should terminate in a final examination conducted by the university and be succeeded by a compulsory year of house appointments, on satisfactory completion of which the student would be admitted to the *Medical Register*. The qualifying examinations conducted by licensing bodies other than the universities should cease. It is pointed out that these cater chiefly for the extramural students in Scotland and for the students of the London medical schools. It is considered that if the Universities of Oxford, Cambridge, and London make their examinations conform more to the type of internal examination held elsewhere, then there should be no need for these extra examinations, which may interfere with the teaching programme of the school and which cost the student money. The committee feels that the overhaul of the whole undergraduate curriculum and a reduction in its content are so important that their accomplishment might be made a condition of any increase in the Exchequer grant for undergraduate medical education. The initiative in this matter is referred to the General Medical Council.

No reform in undergraduate medical education can be effected without the provision of proper machinery and facilities for postgraduate study. Recommendations in this respect may be considered under two heads: those for the training of teachers and specialists and those for general practitioners. For specialists and consultants the committee accepts the recommendations of the Royal Colleges that five years' training after registration is necessary. These five years are to be spent in paid appointments in general hospitals, scientific laboratories, special hospitals, and abroad. Diplomas in public health, clinical pathology, bacteriology, and tropical medicine should be awarded by the universities, the remainder by the Royal Colleges. It is considered that the only ultimately satisfactory postgraduate training for the general practitioner is his continuous contact with the work of hospitals and specialists through holding suitable clinical assistantships. But for many years refresher courses will be necessary, and these should be organized by the universities having medical faculties, and held if possible at institutions not undertaking undergraduate education. These recommendations imply the development of special hospitals as centres of

postgraduate education and research, and far-reaching proposals are made for the development of the British Postgraduate Medical School in London as a federation of general and special postgraduate institutes. The implementation of these proposals will naturally cost money. The committee estimates that to meet recurrent expenditure on undergraduate and postgraduate medical education the university schools will need additional resources which within 10 years will amount to between £1,750,000 and £2,500,000 a year, depending on expansion to meet a need for more doctors. Capital expenditure on the university medical schools is estimated at pre-war costs to be not less than £5,000,000. Finally, an Exchequer grant of £500,000 to the teaching hospitals is recommended provisionally as payment for the extra costs incidental to the provision of facilities for teaching and research. All these grants should be made through the Universities Grants Committee.

The present arrangements for medical education may be likened to a neglected garden, and these proposals to the plans of the gardener to remove weeds and dead wood and encourage growth where it promises to be productive. If the plans are carried out we may anticipate that the garden will be tidy, decorative, and above all productive. Two chief obstacles lie in the way. The first is the expense, in view of the uncertain economic condition of the country in the post-war period. But considering the relatively small sums involved, and the advantages that would be reaped by its children and its children's children, it would be short-sighted of the nation to allow difficulties of this kind to stand in the way. The second obstacle is the men. Teachers of medical students are to be given the tools so that they can finish the job. But unfortunately the post-war years will see a greater dearth of trained teachers than there has been since the end of the last war. Since 1939, staffs, particularly in the clinical departments, have been cut to the bone, and the best young men have been absorbed in the Services. If, then, the opportunity is to be taken, it is essential that our medical schools should begin as soon as possible to make more junior teaching and research appointments. The men must be trained now so that they can use the tools.

THE WIDER DISTRIBUTION OF PENICILLIN

It has been made known in Parliament and otherwise through the lay press that penicillin is being freely used for the treatment of casualties from Normandy and is available also for the treatment of civilians injured in air raids. We are now permitted to give some account of the arrangements which have been made for this treatment, as they are contained in instructions for it issued by the War Office and the Ministry of Health. The available supplies have been enormously augmented by the generosity of the United States, and the policy adopted has been to give full doses of penicillin intramuscularly forward of the C.C.S. level and during transit to all wounded who are considered liable to develop gas gangrene or severe sepsis. Four types of wound are defined which are to be regarded as subject to this risk: those involving

extensive laceration, or destruction of muscle; those heavily contaminated or containing foreign bodies; those involving interference with the blood supply of a limb; and any wounds in cases which have "lain out" for a long period. A yellow label with the letters "PEN" is attached to such cases in Normandy, and, following an initial dose of 90,000 to 100,000 units, the administration of a maintenance dose of 45,000 to 50,000 units is continued at intervals of 4 to 5 hours during transit. When the man is disembarked in England the continuation of this treatment becomes the responsibility of the E.M.S., and the instructions issued provide for its administration in hospital trains and transit hospitals. On arrival at a base hospital, where definitive surgery can be undertaken, the continuation of penicillin treatment may or may not be necessary. It will be extremely interesting to hear what are the results of this boldly conceived experiment in chemoprophylaxis. We may assume that penicillin will also be used for the treatment of wound infections on the lines, based on experience in Italy, which was described by Lieut.-Col. J. S. Jeffrey and Major Scott Thomson in our issue of July 1.

Penicillin is also being supplied to E.M.S. hospitals for the treatment of air-raid casualties. Although every effort has been made to train the persons who will now be concerned in the use of penicillin by means of short courses of instruction at the research centre established last year by the Penicillin Clinical Trials Committee of the M.R.C., there must now be many hospitals where penicillin is available whose staffs have only a very limited experience of its use. This is therefore an appropriate time to repeat the warning often given by those most intimate with this remarkable substance—that it requires intelligent and most careful handling if it is to achieve its purpose. In the first place, unlike most ordinary antiseptics, it is not self-sterilizing. There are many bacteria, including non-pathogenic species commonly found in air and dust, which not only are unaffected by it but will actually cause its decomposition. If accidentally contaminated with such an organism as *Ps. pyocyanea*—an occurrence by no means unknown—a solution of penicillin may become a vehicle of infection and thus perhaps do far more harm than good. It is therefore a first essential that solutions and other preparations of penicillin shall be made up for clinical use by someone fully experienced in the precautions necessary for preventing accidental contamination. A full knowledge of the factors governing its stability and of substances with which it is incompatible is also necessary. From the purely surgical standpoint the main pitfall is overestimating the powers of penicillin and expecting it to do what can be done only by surgery. Penicillin is only an adjunct, however valuable, to good surgical treatment, and does not replace it in any way. Apart from this, success depends mainly on the choice of suitable cases for treatment. Although these can be defined in clinical terms, particularly when the aim is prophylaxis, it should never be forgotten, at least in the treatment of established infection, that what matters is not so much the nature of the lesion as the identity of the micro-organism causing it. Penicillin acts to a useful degree only on certain bacterial species, and among some of them even to a varying extent

on different strains. A bacteriological diagnosis is therefore highly desirable, accompanied if possible by a determination of the degree of sensitivity of the patient's own organism to penicillin. It is for this reason that the bacteriologist has played a leading part in the conduct of penicillin treatment, and has usually had a considerable say in its control. His services are indispensable in deciding whether a case is suitable for treatment—unless this is given at an early stage and purely as a measure of prophylaxis—and for reasons already stated he may actually have charge of the material and be responsible for its preparation for clinical use. It is highly desirable that one thoroughly responsible person of high professional standing shall take charge of stocks, and if at the same time he is in a position to make a special study of the treatment and its effects his advice can be of value to a number of clinical colleagues whose individual experience may for the time being be less. There is perhaps no form of treatment in which close collaboration between laboratory and wards is more necessary.

A word should be added in defence of the general policy of restriction which has so far governed the use of penicillin—a policy which in some quarters has been criticized. Again for the reasons already given, it was possible to ensure that the limited supplies should be used to the best advantage only by confining their release to hospitals where a special study of the treatment could be made. These were at first few in number, but as experience was gained and knowledge diffused, both by the publication of methods and results and by instruction given to the staffs of other hospitals, their numbers have increased lately with such rapidity that they include a majority of those dealing with casualties. If penicillin had been more freely available at an early stage, and used by those unfamiliar with its limitations as well as its powers, there is no doubt that a great deal would have been wasted in treating unsuitable cases, thus depriving other patients of it who in fact have benefited. Some such restriction must clearly continue until penicillin becomes available through ordinary commercial sources of supply. We are informed that a limited allocation of British-made penicillin will shortly be available for civilian use. This will be provided for the time being at Government expense, and there should therefore be no complaint if the control of its distribution is such as to ensure so far as possible that it be used to the best advantage.

PREGNANCY AND RHEUMATIC HEART DISEASE

There is general agreement that pregnancy may seriously aggravate the condition of a heart already diseased, especially by rheumatic carditis. The subject has been admirably surveyed by Hamilton and Thomson.¹ The ultimate effect of pregnancy and motherhood on women with heart disease has hitherto not been so widely studied, but Boyer and Nadas² have now filled this gap in our knowledge with a careful clinical and post-mortem study of 152 women who died from congestive heart failure.

¹ Hamilton, B. E., and Thomson, K. J. *The Heart in Pregnancy and the Childbearing Age*, Little Brown and Co., Boston, 1941.

² *Ann. intern. Med.*, 1944, 1, 99.

The authors considered that if pregnancy had any delayed effect on the course of rheumatic heart disease it would be reflected in the age at death from congestive failure alone. They therefore excluded cases with complications lethal in themselves, patients dying of congestive failure precipitated by or during the course of pregnancy, and those dying before the age of 18. They found the average age of death from congestive heart failure to be significantly greater in women who had borne children (103 cases) than in nulliparae (49 cases). But this seems to be due to the inclusion in the latter group of those quickly fatal cases of heart disease in which the opportunity for conception was consequently absent. When those patients living to the end of reproductive life—40 years of age—are alone considered, the average age of death in the parous and nulliparous groups is "practically and statistically identical." Objection may be raised to using nulliparous patients as controls because of the possibility that only women in good health marry and have children. Without admitting the validity of such criticism the authors made the further comparison using only male patients. It then became apparent that there was no sex difference in the average age of death from congestive heart failure. In patients who survived to the age of 40 the average age of death was practically identical in parous females (49.8 years), nulliparous females (49.7 years), and males (50.1 years).

Boyer and Nadas found no post-mortem evidence to suggest that the increased "load" of pregnancies and motherhood caused any appreciable increase in cardiac hypertrophy. So they conclude that pregnancy has no delayed deleterious effect on the course of rheumatic heart disease.

Attention must therefore be focused on the assessment of the immediate risk of pregnancy, labour, and the immediate post-partum period. The following points may be taken as indicating an unfavourable prognosis: (1) a history of previous congestive heart failure; (2) Class 2 B or 3 (New York Heart Association Classification) cases, and in particular patients with auricular fibrillation; (3) age over 35 (Gorenberg and McGleary³ say age over 30); (4) heart disease complicated by some other pathological condition. During the first nine lunar months of pregnancy the steadily increasing blood volume is a growing burden on the damaged heart⁴; in the last month this burden is lessened. Most cases of congestive heart failure are seen during the antenatal period, and it is during this time and in the immediate post-partum period that the greatest care and attention should be directed towards the prevention of those factors which might lead to cardiac decompensation. Rest at the onset of any untoward symptoms should be the invariable rule. No women need be debarred from pregnancy because of supposed delayed ill effects: it is the immediate risk that is important.

PROTECTION OF RADIUM DIAL PAINTERS

The gross hazards which led to the tragic results of the industrial use of radium in New Jersey during the last war no longer exist. With proper precautions, enforceable in this country under the Factories (Luminizing) Health and Safety Provisions) Order of 1942, and minutely carried out, no such serious injury could or should occur. But the human factor is sometimes potent in defeating the most stringent regulations, and for this reason emphasis on further preventive measures of highly technical procedure⁵ and on "good housekeeping,"⁶ as distinct from

provision of preventive equipment, is both timely and necessary. Radium paint used for self-luminous dials and other instruments consists of a mixture of zinc sulphide crystals with a small amount of a radium salt. Radium, in however small amount, is constantly disintegrating, and during the process emits alpha radiation and the gas radon, while its decay products in their turn emit alpha, beta, and gamma radiation. The danger to radium dial painters from gamma radiation is not great, since the tolerance dose for whole-body exposure (0.1 roentgen per day) delivered by 1.45 mg. of radium at a distance of 1 foot would be exceeded only by much larger quantities of radium paint than are at present permitted to be handled at one time. The risk of accumulation of radium in the body from ingestion of small amounts of paint from contaminated hands, and even more from inhalation of radio-active dust, cannot, however, be regarded as negligible. In America it has already been found that in spite of adequate precautions 15% of all personnel do accumulate more than the tolerance dose, which is tentatively regarded as 0.1 microgramme of radium fixed in the body.¹ It follows that one of the most potent measures for preventing such accumulation is a routine test which will detect very minute quantities, so that any worker showing an amount exceeding the tolerance dose can be removed from exposure and given a chance to eliminate enough to bring the radium content to a safe level. One such test—the radon content of exhaled air—has been widely instituted in America and begun in this country. Breath samples are taken by causing the luminizer to exhale through a litre flask, care being taken that this is done in a place distant from the radium department and after the worker has been out of contact with radio-active material for at least several hours. Calculating from the tidal respiratory volume, the known rate of production of radon by radium, and the fraction of radon exhaled in average cases of chronic radium poisoning, it can be shown that about 1.1 micro-micro-curies of radon per litre of exhaled air represents 0.1 microgramme of radium in the body. Such an amount is said to represent 100% of the tolerance value of radium. Samples of room air can be analysed in the same way and thus a check kept on the effectiveness of the mechanical exhaust ventilation in keeping the radon content below the tolerance level. Another very sensitive technique for measuring the radium in the body by detecting gamma-radiation outside it is also now possible, the sum of this and of the amount estimated from the exhaled air representing the total amount fixed. Thus, workers who through individual carelessness or faulty technique do show the early danger sign of radium accumulation can be prevented from acquiring an amount likely to give rise to trouble in later years.

Carelessness and faulty technique are almost invariably a matter of "bad housekeeping," and can be avoided only by strict supervision, instruction, and constant attention to detail. Contamination of the hands from unsuitable paint containers or from insufficient cleansing of the hands and nails after work is a fruitful source of unsuspected ingestion. Inhalation of dust, even when no actual powder is brought into the room, is specially apt to occur when small splashes of paint on floor and benches are allowed to dry and be rubbed into powder. A striking demonstration of this possibility can be given by examining the work-room under an ultra-violet lamp. Once seen, the need for strict cleansing by a wet method usually requires no further emphasis. These and other details of working habit and equipment are the essence of protection of dial painters against injury, and if satisfactorily attended to should in time eliminate even the 15% of cases showing accumulation of radium as revealed by the exhaled air test.

THE TRAINING OF DOCTORS

REPORT BY THE GOODENOUGH COMMITTEE

The report of the Interdepartmental Committee on Medical Schools, under the chairmanship of Sir William Goodenough, has been published this week by the Ministry of Health and the Department of Health for Scotland.¹ The report is unanimous. It is signed by the chairman, by Sir John Stopford (vice-chairman), Prof. T. R. Elliott, Dr. A. M. H. Gray, Prof. James Hendry, Prof. A. V. Hill, Sir Wilson Jameson, Prof. J. R. Learmonth, Sir Ernest Pooley, and Dr. Janet Vaughan. Fundamental changes in the training of doctors to meet the requirements of a comprehensive National Health Service underlie the committee's recommendations, which are the outcome of a review, occupying two years, of the organization of medical education. The main proposals are briefly summarized below.

Radical Changes Proposed

The committee recommends: (1) Drastic overhaul of undergraduate training; more attention to be paid to social medicine, the promotion of health, and the prevention, as well as cure, of disease, to children's health, and to mental health. (2) Co-education in all medical schools, and sex equality in hospital appointments. (3) Greatly increased Exchequer grants for medical education and research, and more financial help for students. (4) Reform of the examination system. (5) Compulsory hospital appointments after qualification and before entry into independent practice. (6) Changes in the policies and organization of medical schools and teaching hospitals; more whole-time teachers, and salaries for part-time teachers. (7) A comprehensive system for the training of specialists. (8) Development in London of a world centre for postgraduate medical education and research. (9) Linking of all major hospitals with the teaching centres.

The committee says:

"Properly planned and carefully conducted medical education is the essential foundation of a comprehensive health service. . . . The spirit of education must permeate the whole of the health service. One of the principal aims of national policy should be to secure for everyone the highest possible standard of physical and mental health. . . . The achievement of this aim would establish a nation whose citizens were of good heart to enjoy the present and to confront their problems and difficulties with determined zest. By becoming advisers on health both to individuals and to the community, medical practitioners will have to bear much of the responsibility for ensuring this result and, by means of undergraduate and postgraduate training, must be provided with the knowledge and guidance necessary to enable them to carry out this important work. The present system of medical education is seriously deficient in this respect. To the neglect of the promotion of health, medical practice—and consequently medical education—has been concerned primarily with disease, chiefly as it affects individuals. A radical reorientation of medical education and practice is essential, and we believe that both medical practitioners and medical students are ready for it."

The changes in medical education necessary to meet the requirements of a comprehensive National Health Service must take some time to become fully effective. Many of the reforms proposed depend upon the building up of an adequate supply of teachers, a change of outlook on the part of teachers and examiners; and the remedying of serious deficiencies in accommodation and equipment.

Increased expenditure is necessary to remedy the defects in the present arrangements, to secure provision for more medical students, and to develop postgraduate education and research. The committee estimates that, including the outlay of teaching hospitals on facilities for teaching and research, the capital expenditure that should be incurred may within ten years amount to £10,000,000 at pre-war costs. In addition, the amount of recurrent grants will have to be increased yearly from £700,000 a year, the approximate amount before the war, until within ten years it reaches between £3,000,000 and £4,000,000 a year at pre-war values. At this level recurrent grants would represent about 2% of the estimated cost in the

first year of the National Health Service. The committee is confident that these sums will be regarded as a reasonable price for the community to pay for a service vital to the promotion of national health.

Needs of the Future General Practitioner

The committee considers that the training of medical students on modern lines can be conducted only under the aegis of a university and in institutions that conform to university standards. It should provide the student with a university education on broad and liberal lines. The type of instruction should have a definite bias towards the needs of the future general practitioner. Improvements in the organization of medical schools and teaching hospitals must be accompanied by a ruthless pruning of the medical curriculum and an overhaul of the system of examinations. Examinations must be the servant and not the master of the course of training, and reforms in medical education will be largely sterile unless the system of examinations conforms with them. In order that the burden of final examinations may be relieved and students encouraged to pay proper attention to all parts of the training, it is suggested that a system of "internal" departmental examinations in suitable subjects should be instituted as a complement to the final examination. One of the most important recommendations is that each student, after passing his qualifying examination and before being admitted to the *Medical Register* and allowed to enter independent practice, should complete a 12-months period of appointments in hospital.

"A fundamental and urgent reform is to secure that the main emphasis during the training is on basic principles and methods, and that due regard is given to the scientific foundation and framework of medicine. If students are to be trained effectively and are to be properly equipped for practice as family doctors, general medicine must form the most important part of their clinical training. More attention must be given to minor ailments, the more common diseases and the early stages of disease, to chronic diseases, to infectious diseases, to rehabilitation."

Social Medicine, Child Health, Mental Health

In regard to the three interrelated subjects of social medicine, child health, and mental hygiene the committee says:

"In most schools the attention paid to social medicine, the promotion of health, and the prevention of disease is often perfunctory and largely divorced from the rest of the student's training. If medical students are to be fitted to become health advisers and members of a National Health Service, the ideas of social medicine must permeate the whole of medical education. A new orientation of medical education, a big expansion of the social work of teaching hospitals, and radical changes in the outlook and methods of most of the teachers are involved."

"To safeguard its own future, the nation will have to improve its provision for the welfare of children. These improvements will extend beyond the immediate sphere of medicine, but medical practitioners will have to play a leading part in raising the health of the children to the highest possible level. Generally in the medical schools the teaching about children has been inadequate and only faint interest has been taken in the subject. The deficiencies have been most serious in respect of child health and normal development. In many schools the experience which students gain of maternity work falls far short of what is necessary."

"Whether he is dealing with problems of health or sickness, the medical practitioner cannot fully understand his patients or advise and treat them adequately unless he pays due attention to their psychological background. The training in psychiatry has failed to keep pace with the growing realization of the important place which the subject should occupy in medical thought and practice. In future every medical teaching centre must have an adequate department of psychiatry, the work and teaching of which are related to the work and teaching of the other departments. These departments cannot be established until there is an adequate supply of competent teachers of psychiatry. The training of such teachers is a major and urgent need."

Women Medical Students

The committee holds that unsuitability for a medical career should be the sole barrier to admission to a medical school. In the interests of the public and of the medical profession, co-education, which has been the normal and successful practice for many years in all medical schools in Great Britain outside London, should become the practice in every school. It is recommended for Government decision that the payment to

¹ H.M. Stationery Office, York House, Kingsway, London, W.C.; price 4s. 6d., post free 4s. 10d.

any school of Exchequer grants in aid of medical education should be conditional upon the school being co-educational and admitting a reasonable proportion of women students. Every possible step should be taken to see that all hospital appointments of qualified practitioners are filled by open competition and that the sex of the applicant is not a bar to appointment.

Financial Help for Students

In England and Wales, but not in Scotland, there is a marked difference between the proportion of medical students and the proportion of students in the faculties of arts and science who receive financial assistance. While the faculties of medicine of Scottish universities draw students from all classes of the community, medical students in England and Wales are not recruited from so wide a field as are students in other branches of the universities. The main causes seem to be: (1) misconceptions on the part of parents regarding the amount of assistance that can be obtained towards the cost of medical education; (2) a lack of encouragement to secondary-school pupils to take up medicine as a career.

The committee recommends that grants to medical students should be adequate in amount and should extend over the whole of the period of training. The arrangements for scholarships and grants should be simplified, and medical schools should have larger funds at their disposal to help students and to encourage graduates in other faculties to study medicine.

"It must be brought home to boys and girls, to their parents and school teachers, that there is no profession offering a wider range of interests than medicine; and that children with ability need not be debarred from entering the profession through lack of money."

Selection of students should not be based on examination results alone. There should be an interview before acceptance; and the medical schools should also consider the extent to which aptitude tests can usefully be applied. The selection machinery should be supplemented by arrangements to weed out as early in the course as possible (particularly in the first year) those students who prove unsuitable.

Supply of Doctors

The number of doctors in civilian practice in Great Britain increased steadily before the war. It is expected that the number will continue to grow for some years to come. In a report on medical man-power the Government actuary calculates that if the total entry of students is enlarged to 2,500 or more, the supply of doctors in civilian practice in Great Britain will grow to at least 50,000 by 1953 and 55,000 by 1958 (increases of approximately 5,000 and 10,000 respectively). This increase in the entry of students is within the capacity of existing schools, and the committee suggests that the first objective should be an expansion of those existing university schools which are below an economic size (normally 100 students a year) rather than the creation of new schools.

Medical Teaching Centres

The full recommendations of the Goodenough Committee are set out in the general summary of its report occupying over 27 pages. They include the following. The unit of organization for the national system of undergraduate medical education should be a medical teaching centre, consisting of a university medical school, a group of teaching hospitals (parent and associated) in as close proximity as possible to the medical school, and such clinics of the health service of the district as should be used for teaching purposes. Ideally—and the committee thinks this is an attainable objective—they should form a compact geographical unit. While the governing body of each constituent institution of a teaching centre retains full authority in its own field of responsibility, the policy, administration, and activities of the constituent parts should be so interrelated that the institutions function as one in the field of medical education and research.

Every medical school should be a university medical school in the sense that it is an integral part—i.e., faculty, college, or school—of a university. This principle should apply to existing schools and to any new schools which it may be found expedient to establish. There should be a common advisory

machinery used by all parts of a medical teaching centre for the selection of medical staff other than junior grades. Grants from public funds for the educational work of the centre should be received through university channels.

The three extramural schools in Scotland cannot meet the modern requirements of medical education efficiently, and it is recommended that they should cease to train medical students. The West London Hospital Medical School, the only non-university medical school in England, should not continue, beyond possibly the next four or five years, to train undergraduate medical students.

A new pattern of staffing is necessary. More whole-time appointments and the payment of salaries to clinical teachers in respect of defined duties are among the changes proposed. The adoption of new machinery in selecting teachers and staff of teaching hospitals is also recommended, together with a reorganization of the educational work of the clinical departments based on the idea of each clinical division having an academic head.

Medical Schools: Size and Distribution

The present unequal distribution of medical schools and students is recognized, and long-term proposals are made with a view to a decrease in the large number of students trained in Scotland, particularly in Edinburgh and Glasgow, and in Central London. To minimize the concentration of schools in the centre of London, Charing Cross Hospital should move as soon as is practicable to a site in Middlesex, and St. George's to a site in, say, South London, where there is an urgent need for hospital accommodation. It is suggested that the London School of Medicine for Women and the Royal Free Hospital should also consider moving further from the centre of London. Provided that the necessary additions are made to the teaching staffs, accommodation, and equipment, all the existing medical schools in the English Provinces and Wales could be expanded without detriment to the standard of training provided. These schools should enlarge their entries of students as quickly as possible.

"The medical schools should regard themselves as under a definite obligation to do all in their power to meet the need for more doctors, but they should avoid any premature increase in the number of medical students inconsistent with the maintenance of a proper standard of training. To sacrifice the standard of training in any way would be gravely detrimental to the future vitality and success of the health service."

The general conclusions of the committee regarding the establishment of new medical schools are:

- (1) The financial resources and the suitably qualified teachers likely to be available will be wholly needed for a long time for the development of existing schools to their full capacity.
- (2) To provide a stimulus to the hospital services of an area is not a sufficient reason in itself for the establishment of a medical school. There must first be proof of a national need for another school, and it must be clear that a school at least of the standard of existing schools can be provided.
- (3) Any proposal to develop a medical school at one of the independent university colleges should be deferred until such time as the university college concerned has become fully established as a university.
- (4) The undergraduate medical schools in London are already too numerous to warrant an addition to their number. The aim should be to secure better facilities for the existing schools and to improve and develop the exceptional facilities of London for postgraduate medical education.

Postgraduate Education and Research

The kind of postgraduate training and experience required by intending specialists and the means whereby it can be obtained have been examined by the committee as questions of great importance both in the operation of the health service and in the sphere of medical education. On the assumption that the qualification and standards of specialists are determined by some central machinery and that the primary requisite will be approved postgraduate training and experience extending over not less than 4 to 5 years after registration, the committee makes various suggestions, which include the following:

- (1) While holding hospital appointments the intending specialist should be regarded as a trainee and be given adequate time for

reading, reflection, and research. He must not be overburdened with routine work and he must be adequately remunerated.

(2) As a rule, before he begins to specialize, he should have at least six months' resident clinical experience of general medicine or surgery.

(3) Every trainee should have the opportunity to devote himself for a period to the extension of his scientific knowledge by laboratory work and study, and provision should be made, by such means as travelling fellowships, for trainees to obtain the benefit of working for a time in suitable hospitals and medical schools abroad.

The committee declares that postgraduate study should be a regular and recognized feature of general practice. Periodic intensive refresher courses should be regarded largely as a short-term expedient; the long-term policy should be to bring general practitioners by various means, such as clinical assistantships, into regular association with the work of hospitals and of specialists.

Postgraduate Institutes.—A scheme is outlined for the development of the exceptional resources of London for the postgraduate education of medical practitioners from all parts of the world. This scheme involves the reconstitution of the British Postgraduate Medical School on a federal basis embracing a comprehensive range of postgraduate institutes in all branches of medicine. The committee points out that there is at present a singular lack in Great Britain of facilities for postgraduate training in special subjects, and recommends the development of a number of institutes in the special subjects to serve as the spearhead of postgraduate education and research in those subjects. The universities, in consultation with the professional and scientific bodies concerned, should agree on a national plan.

Medical Research.—On this subject the committee says that a community wishing to promote research must first find and train the men who have the ability and impulse for scientific inquiry. It must then create the most favourable conditions for their work and give them the tools they need. Young research workers should mainly recruit themselves, their careers being closely watched and guided. When a worker has proved his research ability and has chosen research as a career, he should be given reasonable security in this career. Medical schools, teaching hospitals, and postgraduate institutes have three important functions in relation to medical research: (i) to discover and train future research workers; (ii) to encourage and facilitate original investigations by members of their teaching staffs; and (iii) to house special research units and workers. Public grants to medical schools and teaching hospitals must include basic research grants, and extra grants will also be needed from public and private sources for the support of special investigations.

Medical Teaching Centres and the Health Service

Medical schools as partners in the National Health Service should, the committee says, have an appropriate place in the administration of the service. If Central Health Service Councils are established for England and Wales and for Scotland, the universities in the respective countries should be given adequate representation.

Though they will be available for consultation and advice, specialists on the staff of teaching hospitals, if they are to give as much time as they should to the clinical and educational work of the teaching centres, will not be able to undertake regular duties in other hospitals. As a general rule their hospital work, including consultations with members of the staffs of other hospitals or with general practitioners, should be conducted in the hospitals of the teaching centre. The linkage of non-teaching hospitals with the teaching centre must be brought about by means of educational associations developed between a medical teaching centre and all the major hospitals in a wide area around. These associations will evolve in part out of the arrangements made in respect of pre-registration house appointments and in part out of provision for refresher courses for general practitioners, hospital appointments for intending specialists, and other forms of postgraduate education. To help the hospital service generally, and to facilitate a better distribution of specialists, medical teaching centres should make it an established principle that tenure of a post in a non-teaching hospital is regarded as a qualification in favour of an applicant for appointment to a teaching hospital.

Nova et Vetera

Dr. WILLIAM GILBERT (1544-1603)

A recent meeting of the History Section of the Royal Society of Medicine was devoted to a discussion of the place of William Gilbert in medicine and in science, and the occasion was the celebration of the quatercentenary of his birth.

Sir Walter Langdon-Brown dealt with Gilbert's life and his place in the medical world of his time. He said that recently the Dean of one of our cathedrals called on an undergraduate of St. John's College, Cambridge, and, observing the arms of William Gilbert on the walls, he asked the undergraduate who Gilbert was. Neither of them had heard of him. Half an hour later Sir Walter had the satisfaction of showing the Dean a copy of the first edition of *De Magnete*. Gilbert was born in Colchester, and all his life he remained proud of this association. The date of his birth is given at varying dates from 1540 to 1544, but there is new evidence that he was really born in the latter year. He matriculated at St. John's, and later became a "physic fellow." In 1570 he began a three-years tour of Italy, and returned as a champion of the experimental method. He settled in practice close to the first College of Physicians and soon became prominent in his profession. He was a Censor of the College for nine years, Treasurer for eight, and became President in 1600. He was physician to Queen Elizabeth and attended her in her last illness. Gilbert died in 1603, probably of the plague. In his will he bequeathed his library, his globes, his instruments and cabinet of minerals to the College. As a physician Gilbert was very sceptical about the ridiculous claims made for remedies: as he says, "Thus do the smatterers cross swords together and puzzle inquiring minds by their vain conjectures." During his time there was a change in the outlook and function of the universities. His insistence on observation and experiment, his scorn for reliance on mere authority, his hatred of shams and quackery, were not without their effect in combating the pestilential influence of astrology on medicine. He was the first of English modern scientists.

Prof. Sydney Chapman dealt with Gilbert and the science of his time. Apart altogether from his medical work, he was always an ardent student of science. In his early days he studied chemistry, reputedly with success, and throughout his life he paid great attention to astronomy. He was the first Englishman to accept and propagate the revolutionary view of Copernicus and of Giordano Bruno. Despite the time which he devoted to his medical and scientific work, he was no recluse, and his friends included physicians, astronomers, mathematicians, and sailors. He was a friend of Drake.

It is in the field of magnetism and electricity that he has earned enduring fame as the great founder. Gilbert's researches on these subjects extended over eighteen years, and the results were published in *De Magnete, magneticisque corporibus, et de magno magnete tellure* . . . (on the magnet and magnetized bodies, and on the great magnet, the earth), London, 1600. Gilbert paid his own expenses for his work, according to some about £5,000. A great predecessor was Petrus Peregrinus, who three centuries earlier had recognized the poles of a loadstone, and Robert Norman of Limehouse a few years earlier had discovered the magnetic dip. Gilbert showed that the earth is simply a great spherical magnet, and by his experiments he founded the science of geomagnetism. He greatly extended the range of substances known to be magnetic, and he distinguished clearly between magnetic and electric reactions. He recognized the "orb of virtue" (magnetic field), investigated the influence of physical agents on magnets, and collected data as to the direction of the compass in different regions. By his pioneer work on electricity he recognized definite classes of electrics and non-electrics; he showed that damp weather hinders electrification, and that the electric attracts bodies themselves and not the intervening air; and he invented the non-magnetic electroscope. He asserted that the magnetic axis remains invariably in the earth, but he was wrong—as Newton later showed—when he asserted that the earth's rotation is due to its magnetism.

Gilbert dissipated much of the superstition that had hitherto been associated with the loadstone. His book made three great contributions to science: the ordering and extension of magnetic knowledge; the foundation of knowledge of electricity; and his conception of the earth as a great magnet. It was praised by men like Galileo and Kepler, and he has long been recognized as "the father of the sciences of geomagnetism and electricity." E. A. U.

The British Hospitals Association has issued from 12, Grosvenor Crescent, S.W.1, two printed documents, one being a suggested form of constitution for Nurses' Representative Councils prepared jointly by the Association and the Royal College of Nursing on the advice of their liaison committee, and the other giving model forms of conditions of service and agreement for the engagement of student nurses by hospitals.

Correspondence

Chartered Physiotherapists

SIR,—The Chartered Society of Physiotherapy, having recently received permission from the Privy Council to change its name from the Chartered Society of Massage and Medical Gymnastics, has decided that the time is fast approaching when it must make some drastic changes in the training of its future members, and it is therefore proposed to increase the length of training to three years.

The time would appear propitious to make clear the difference between chartered physiotherapists and those who advertise themselves as qualified by correspondence, short courses, etc., to practise this form of physical treatment. In order to become chartered physiotherapists candidates are required to undergo a full-time training of two and a half years' duration at one of the recognized schools of physiotherapy attached to hospitals (usually those with medical schools). They must have gained the school certificate or its equivalent, and have some knowledge of chemistry, physics, and general science. During the training the average working day is 6 to 7 hours. After about three months' concentrated preliminary training 2 to 3 hours daily are spent in the wards and out-patient departments of some large hospital. This work is carried on under trained supervision and often under the direction of a specialist in physical medicine. Experience is gained by attendance at clinics examining orthopaedic cases, recent injuries, and other surgical and medical conditions. The remainder of the day is devoted to theoretical and practical lectures and demonstrations. All private study has to be done in the evenings and at week-ends, and the average student finds a minimum of 14 hours a week necessary to keep up with the work.

The examinations for the certificates of the Chartered Society include four 3-hour papers in anatomy, physiology, kinesiology, electrotherapy, theory of massage, and the application of these subjects to medical, surgical, orthopaedic, and other cases, and about two hours' practical and oral examination in the same subjects. The examiners include professors of anatomy, members of the medical profession interested in physical medicine, and Chartered Society of Physiotherapy teachers of not less than five years' standing. In order to maintain the high professional and ethical standards of the Chartered Society, chartered physiotherapists are required to give a written undertaking to work only under the direction of registered medical practitioners and to conform to certain other rules.—I am, etc.,

HERBERT L. EASON.

Chairman of Council, Chartered Society of Physiotherapy.
Tavistock House (North), W.C.1.

Sedatives for the "Bombed"

SIR,—Being in frequent contact with children at rest centres or at evacuation sessions who have been bombed, I feel that more sedation therapy might be of great value. One child of 18 months, who had been blown out into the garden, was unmanageable when the siren went and had not slept adequately several days and nights. On sod. brom. 3 gr. t.d.s. and at night, and chloral hyd. 1 gr. 5 in die, he slept almost continuously for two days and nights, then, renewed, able to smile and to ignore the sirens, he remained fit so long as he continued on sedation. If the mother took him out and he missed his dosage the old symptoms of screaming returned. He was finally evacuated, laughing and cheerful after a dose of sod. brom. 5 gr., chloral hyd. 1½ gr. Several other children, some of whom had been in hospital with injuries, on rejoining their families at the rest centre were in a highly nervous, tense state. The mothers have been very grateful for sedative treatment. The children are as lively as crickets on it, and their nervous tension is released.

In private practice among adults I have used luminal 1½ gr. at night as preventive of the fatigue that accompanies nervous tension. Some of these women had tiny children in their care. They have all been very grateful, and have said how much better they felt on it. One week's treatment and they got their "second wind" and were able to continue without. On

admission to rest centres after bombing the adults get sod. brom. 12 gr., sod. barbit. 2 gr., repeated as required.

I have to thank Dr. Yellowlees and Dr. McFarlane for their encouragement.—I am, etc.,

London, S.W.

M. STEWART.

Site for Intramuscular Injection

SIR,—I was very much pleased to see that Prof. Grey Turner has made use of his great influence again to advocate abandonment of the gluteal site for intramuscular injections and recommends the outer side of the thigh as the proper site for such procedure. No doubt many surgeons do give instructions to their juniors and their nurses in accordance with Prof. Grey Turner's recommendations, but in our teaching hospitals, apparently, students are still taught to inject into the gluteal muscles. Only the other day a student at one of our great London hospitals told me that he had been taught to do this.

It is difficult to see why the gluteal region was ever chosen for this purpose. Apart from the major dangers to which Prof. Grey Turner calls attention, the gluteal muscles are often covered with a thick layer of fat, and it is not infrequent for the injection to be given into this layer and not into the muscles. The result is often a deep slough, which takes weeks to separate, and if the patient is confined to bed the resulting discomfort can be readily imagined. By mapping out on the outer side of both thighs three zones—upper, middle, and lower—six areas free from any dangerous structures are available for injection, and a nurse can ring the changes many times without using the same site more than once. Recently, for particular reasons, I had to order a course of sulphonamide intramuscular injections in a medical colleague. No fewer than fifty injections were given in this way without causing more than trifling discomfort.

I trust that the practice so forcibly advocated by Prof. Grey Turner will soon become the recognized teaching.—I am, etc.,

SIDNEY BOYD.

London, W.

SIR,—As one who has administered perhaps more intramuscular injections than any other man living, I applaud Prof. Grey Turner's letter (July 8, p. 56) emphasizing the undesirability of choosing the central buttock as the site for any deep injection. Personally, I should have thought that the piercing of the sciatic nerve would sufficiently warn the operator to proceed no further; but such an irritating substance as quinine might surely cause neuritis, even if the nerve were not actually penetrated by the needle.

There is another danger when substances dissolved or suspended in oil are injected deeply in or around the sciatic notch—that of oil embolus. Here the needle will be travelling in the direction of larger veins and may deliver the oil right into the lumen of one of them. The effect, if not dangerous to life, is extremely disconcerting. The patient, even when anaesthetized, gives a characteristic cough at the instant the plunger is pressed down, shows marked symptoms of shock, and may retch uncontrollably for hours or even days. Five such accidents have occurred in my experience, all of them during injection into the "forbidden area," and I am convinced that when this part of the body (so often the seat of rheumatic fibrositis) requires to be locally injected only such medicaments must be used whose inadvertent introduction into a vein would be a matter of no particular anxiety.—I am, etc.,

G. LAUGHTON SCOTT.

London, W.1.

** In an answer to a query on this subject published under "Any Questions?" (June 12, 1943, p. 716) it was observed: "The tendency nowadays, however, particularly in the case of the sodium salts of the sulphonamide drugs, is to choose the antero-lateral aspect of the thigh (*vastus externus*) as the least dangerous site for intramuscular injection."—ED., B.M.J.

Problem of the Small Bladder

SIR,—May I have the privilege of a little space in your columns to draw attention to the problem of the small muscular bladder in young males, and invite comment and correspondence on this condition from more experienced and competent urologists. It is apparently little known, and I cannot find much about it in the textbooks or literature. The

typical picture is that of a young male who gives a history of frequency and urgency all his life. The stream is good and there is no pain, but he finds he must rise several times at night and even occasionally wets his bed. Conditions in the Army usually force him to seek advice and many of these patients are sent in for urinary investigation as cystitis or enuresis. Recently I have also investigated a boy of 14 and a girl of 10.

One is inclined to regard these people as neurotics after taking their history, and to conclude that they have a bladder neurosis bad enough to disturb them even during sleep. The urine is usually clear and sterile and the stream large and forceful, but the amount passed is rarely more than 10 oz. The most important feature is that there is no residual urine, and this is the first factor to be excluded.

Cystoscopy shows a bladder of small capacity, often no more than 6 to 10 oz., though on occasions I have found it as much as 15 oz. There is very marked trabeculation with prominence of the trigone, and from time to time the whole musculature goes into spasm, forcing urine past the cystoscope, which must be firmly held, or it may be pushed out of the bladder. Renal function is usually excellent. So far as can be determined with the cystoscope or cystourethroscope there is no stenosis or hypertrophy of the internal sphincter urethrae. Intravenous pyelography shows a normal upper urinary tract, but the bladder is usually shown by a small round dense shadow of the excreted substance. We know of course, that prostatic obstruction due to hypertrophy of a tight internal sphincter may cause symptoms quite early in life.

I have always assumed that in these men there should be some dysuria, a slow stream, and evidence of residual urine, and in the later stages even a dilated bladder, but I suppose it is possible that as a reaction to such partial obstruction the bladder muscle may hypertrophy and contract down rather than dilate, thus preventing the accumulation of any residual urine and maintaining a good forceful stream.

One of the problems in urology is to decide whether there is constriction of the internal meatus. The MacCarthy resectoscope will perhaps show it in the majority of cases, but one is hardly justified in passing it as a routine for the purposes of diagnosis. The problem as I see it is as follows. Are these small muscular bladders a handicap which the patient is born with and doomed to tolerate all his life, or is this a hypertrophy secondary to an internal meatus obstruction, and if this is the case can we help these people in the early stages by a perurethral resection of the faulty sphincter? This problem needs public view and consideration and discussion for I presume that other E.M.S. hospitals are no doubt consulted by many similar cases drawn from our fighting Forces. After the war these men may find themselves able to cope with their frequency in civil life and will not so readily seek advice, and never again shall we have such an opportunity of helping these unfortunate people—I am, etc.,

Chelmsford

M D SHEPPARD

Bone-marrow Transfusion in Children

SIR—Replying to the letter from the Alder Hey Hospital (June 17, p. 826), we fully agree that the intravenous technique can be easily acquired by residents on a children's unit. It is a fact, however, that many doctors never have this opportunity.

With increasing experience we have found it desirable to develop alternative methods of parenteral fluid administration such as the scalp vein injection of small quantities of fluid, and the marrow route. The marrow route would seem to be the simplest method at present available, and is therefore reasonably well suited to institutions which do not cater routinely for intravenous therapy in children. We would suggest that the bone marrow drip may be usefully employed for children in the following circumstances:

1. Babies in whom the veins in the usual sites (ankles, wrists, and cubital fossae) have been used. On several occasions we have seen infants sent to this hospital whose veins have been seriously mutilated—even the femoral vein in one case. With these babies it is essential to find an alternative route.

2. Shocked and premature babies in whom the minimum of disturbance is desirable.

3. Patients in whom repeated blood transfusions have been given, or will be required, such as haemophiliacs and aplastic anaemias.

The needle described by Gunson (*Journal* June 3, p. 748) has also proved eminently satisfactory for taking marrow smears from children of all ages. The danger of osteomyelitis should not be forgotten, but the immediate emergency under the above listed circumstances justifies the problematical risk of infection—We are, etc.,

PATIENCE BARCLAY

Hospital for Sick Children, Great Ormond Street, F. L. KING LEWIS

Why Tie the Cord?

SIR—Dr. Price's pertinent question (June 3, p. 772) and subsequent correspondence lead me to record the custom of another tribe (Lokele) of primitive forest folk in the Belgian Congo. The cord is never severed until the placenta is delivered. The mother is then handed a native razor, which she strops on her bare thigh. She then cuts the cord herself, about 8 to 10 in. long, milks out the contained blood, and spits on the end, no ligature is applied.

The strength of conviction against severing the cord while the child, alive or dead, is still joined to its mother is such that I have known a woman brought to hospital after a two-days journey in canoe for removal of retained placenta, to which the dead child was still attached.

The length of cord left probably safeguards against sepsis, for it shrivels in the dry atmosphere of the overheated hut before infection can ascend to the umbilicus. Horror was previously expressed at seeing it cut the regulation 3 to 4 in., and indeed the only case of fatal sepsis I saw in 16 years was in a child born in hospital. It is always difficult to disentangle sense and nonsense in savage custom and superstition, but may it not be that the refusal to separate mother and offspring means that the child gets an extra ounce or two of blood when the placenta is expelled, and that ligation is quite unnecessary at that stage, if ever?—I am, etc.,

Chalfont St. Giles

CLEMENT C CHESTERMAN

SIR—The following experience may be both interesting and amusing.

In the autumn of 1914 I was helping in a large French military hospital in Normandy (in a town now in the central picture). One afternoon the *chef de cuisine* rushed excitedly into a ward where the surgeon and I were dressing a wound and said his wife had given birth to a baby in the kitchen. I seized a tray with a jar of leucures, a bowl of sea-water—strained, boiled, and diluted with ordinary sterile water—this was all the French surgeons used to cleanse the wounds—and we went to the kitchen which was in the dark and gloomy basement. There we found the woman on her back on the scullery floor, also the baby—alive. I put a few ligatures together and knotted them, and on handing them to the surgeon, who was a middle-aged Russian lately practising in Paris, he shook his head and said, "Non non madame pas nécessaire, la!" and having cut the cord some 6 or 8 in. from the umbilicus deftly with a twist knotted it. Then dipping his fingers in the sea-water he pressed on the knot for a minute or so. At this stage the *chef* returned with a bottle of champagne and we four, including the mother, drank to the happy event. The baby thrived so did the mother who was back in the kitchen in a week.—I am, etc.,

G A JACKSON

War Surgery

SIR—With great interest I read General Mitchiner's article (July 8, p. 37) but as an officer i/c Surgical Division of a large and busy general hospital in North Africa during that campaign and as a surgical specialist in France 1914-18 I am also in a position to compare some of the results, and am not in agreement with General Mitchiner on all points.

His remarks on sepsis do not agree with the facts in North Africa, where the wounded arrived at the base with little sepsis after travelling several days, as was the case in the earlier weeks. These men had all had the routine excisions, application of sulphonamides with vaseline-gauze drains, and the parts covered with plaster-of-Paris and it was rare to find a grossly infected wound—such a contrast to what we were used to in 1914-18. Another point of interest was the very

small number of cases of massive gas gangrene, even in the large wounds of the buttock and thigh, although anaerobes were present in some of the cases.

On the matter of amputations, the only criticism we could make was that the forward surgeons had worked hard cleaning up severely damaged tarsal and metatarsal injuries, which reached us in good condition and were eventually sent on to U.K. healing, but with feet which it was difficult to imagine would be weight-bearing and which could with advantage have been amputated at a forward C.C.S.

With regard to burns, of which there were a great number, many accidental, but large numbers coming from among the survivors from the sea, the results of cleaning under anaesthesia, removing dead skin, then applying sulphonamides and covering with vaseline gauze, and with infrequent dressings done only at several days' interval, were very good. Our largest batch was sixty-three survivors from a ship which burned after being torpedoed, nearly all severe, of whom only two died.

In conclusion one can only say that having seen the surgery in two wars, there is no doubt that the wounded man is being exceedingly well treated at the forward centres, and reaches the base in a better condition in this war than in the last.—I am, etc.,

London, W.1.

Clinical View of Shock

SIR,—The symptoms of shock described by Mr. Zachary Cope (July 8, p. 35) and the changes in the body, and particularly in the circulation, are identical with those shown after an injection of histamine, used so often in the treatment of mental disease, even to the flush on the face. Histamine is produced in every form of shock, and it is most significant that a shock-producing body is found in fresh voluntary muscle in shock, where histamine is formed in large quantities but soon disappears. Histamine might therefore be the cause of shock.—I am, etc.,

HORACE HILL, M.R.C.P.,

Laverstock House Mental Hospital, Salisbury. Medical Superintendent.

Repairing the Perineum

SIR,—Miss Josephine Barnes expresses herself as glad of an opportunity of "protesting against the prevalent and pernicious practice of giving a general anaesthetic for repairing the perineum." I trust she will not mind if I use her opening as an opportunity for protesting against the even more prevalent and equally pernicious practice of giving no anaesthetic for this procedure.

As a student at University College Hospital I imagined that I was learning from Prof. Browne the standard way of repairing a perineum. I was amazed, on coming out into the cold world eleven years ago, to find that I was mistaken. The method I had been taught has been a surprise to every midwife that I have encountered! It would appear that the usual approach to the problem is to see it as a most unimportant adjunct to the delivery. "It is all over now, Mrs. Blank, except for a couple of stitches, and we'll soon get those in." Mrs. Blank is then invited by nurse to "bite on this towel," to "hold my hands and scream if you want to," or some such, and a couple of sutures are hopefully whipped in to a struggling patient.

The essential advantage of what I will venture to call the U.C.H. method lies, as I see it, in the possibility it offers of a proper approach to the problem. The repair of a torn perineum is a most important procedure, not lightly to be undertaken. Miss Barnes touches upon the dangers of a deficient perineum. I would add that a sound perineum is more important in maintaining a happy marriage than is a pretty face: he who carelessly spoiled a pretty face would probably have to pay damages to his patient, yet the perineum can be spoiled and no penalty paid!

For a perineum to be properly repaired it is necessary: (1) for the operator to appreciate the importance of his task; (2) for the operation to be painless, so that no matter how long the work takes the patient remains comfortable and co-operative (the U.C.H. technique ensures this); (3) the operator must take his time (the U.C.H. technique allows this);

(4) the operative field must be thoroughly exposed (more like with a leisurely approach to the leisurely operation made possible by the U.C.H. technique); (5) the operator must be comfortable; and (6) the light must be good (how many G. carry a good head-lamp in their midwifery bags?). Miss Barnes says that local infiltration anaesthesia is painless and so May a very average G.P. add, for the benefit of those G. who have not yet ventured to try it, that it is also extremely simple? The satisfaction of having done a thorough (without hurting the patient) more than compensates for extra time taken.

In one other detail the technique as taught to me Prof. Browne differs from that generally used. I was taught to use for each of the interrupted sutures in the skin a twelve inch length of silkworm gut, to leave the ends uncut after tying, and finally to gather the ends together, to knot the bunc and to wrap the knot in sterile gauze. The extra comfort to the patient, as compared with the more generally used method of cutting the silkworm gut short after tying, is immense.—I am, etc.,

West Bromwich.

D. SAKLATVALA.

Results of Colles's Fracture

SIR,—As an old practitioner I write confirming Dr. Abercrombie's remarks about the scandalous abuse of plaster-of-Paris by the bulk of the profession (July 8, p. 55). For years we were taught to start movement of a "Colles's" hand within 48 hours of the fracture, and to continue to do so ever second day for 2 to 3 weeks. Of course we used the old wooden splint with a straight dorsal splint. The result was that within 4 to 5 weeks the patients were about their job as usual. The slight deformity left was of little consequence.

Some years ago you published a letter of mine, instigated by Prof. Hey Groves's letter protesting against the blind use of plaster-of-Paris splinting, and maintaining that if plaster-of-Paris must be used it should be applied in the Croft method—i.e., with a starch bandage that can be slit up for inspection.

An old lady has broken her forearm; at a hospital it has been so mismanaged that it has been replastered four times. A lady slipped in her kitchen and fractured both tibia and fibula three inches above the ankle. It was put into plaster, not touched for three weeks, and on release the whole foot was so badly retracted that operation was undertaken to restore it. Result, gangrene of the foot, which had to be amputated!

The results that I have heard of from this mad dependence on plaster-of-Paris make the old G.P. grieve for the unfortunate public and for the honour of his profession, which in other matters has attained such distinction.—I am, etc.,

VAUGHAN PENDRED.

Wrapping for Biopsy Material

SIR,—The recent shortage of gutta-percha tissue has led to the pathologists' receiving biopsy material wrapped in a variety of very unsatisfactory substitutes. In suggesting a satisfactory wrapping material we feel impelled to recall the great importance of reducing to a minimum the time between the surgical removal of the tissue and its visual examination by the pathologist. When tissues are of such a nature that naked-eye examination gives no indication of the changes likely to be found microscopically, then by all means let them be immediately immersed in fixative solution (such as the one advocated by one of us (A. C. L.) in the *Journal* of Nov. 20, 1943, p. 644). But if they be large in size or otherwise demand the pathologist's scrutiny before fixation (he should be the judge of the type of fixative most suitable for the particular tissue), then it is essential that the tissue be enclosed in a wrapping that is highly water-resistant. It has been found that the variety of transparent wrapping material marketed as "Cellophane M.S.S.T." is a satisfactory and also a cheap substitute for gutta-percha tissue; the thinnest grade—M.S.S.T. 300—is adequately strong and the cheapest, since the material is sold by weight.—We are, etc.,

M. K. GILMOUR.

Glasgow University.

Rheumatic Fever and the Sulphonamides

SIR.—The following case history is of interest in view of the opinion recently stated by a prominent physician that rheumatic fever would in the near future cease to be of importance owing to the prophylactic value of the sulphonamides.

T. W. was admitted to hospital in January, 1944, with an acute suppurative otitis media. He had no history of previous illness of any sort. He was put on to sulphadiazine in the usual dosage, and started to improve immediately, the condition having cleared up by the 10th day, although he was still on the drug. On the next day he developed a painful swollen and tender right sternoclavicular joint which lasted for about 48 hours. During the following week he developed pain, swelling, and tenderness successively in the left shoulder and knee and the right shoulder, with a temperature of 102° and malaise and sweating. The blood sedimentation rate was 46 mm. in 1 hour, and there was a trace of albumin in the urine.

A diagnosis of rheumatic fever was made and the patient was put on to a course of sodium salicylate. He made an uninterrupted recovery from this time, and was discharged on the 47th day of this illness. When seen a week later he was found still to have a mitral systolic murmur which had developed during his stay in hospital, and electrocardiographic evidence of residual myocardial damage.

It will be seen, therefore, that this man was actually at the end of a course of sulphadiazine when he developed an acute first attack of rheumatic fever, which incapacitated him for six weeks and left residual myocardial damage—I am, etc.,

W. S. C. COPENAN.

Chemotherapy in Otitis Media

SIR.—As a general practitioner I find myself in complete agreement with Mr. Steele's views that the early and adequate exhibition of the sulphonamides has revolutionized the treatment and prognosis of otitis media. If Mr. Dingley complains that the sulphonamides are used indiscriminately in these conditions, the answer is "Of course they are." If an empyema thoracis develops it is not evidence that the original pneumonia was wrongly treated with sulphapyridine, nor, I maintain, is it indicative of wrong treatment if an "empyema" of the middle ear develops after sulphonamide treatment of an acute catarrhal otitis media.

There are two dangers against which we must guard—the use of sulphonamide tablets as though they were a special form of aspirin, and the overlooking of the silent mastoiditis. With a realization of the many pitfalls, I agree with Mr. Steele that the general practitioner is the best judge of the value of chemotherapy in otitis media, and that it has replaced the myringotomy as the first line of defence.—I am, etc.,

Cambridg.

F. BROCKINGTON.

SIR.—Further to the interesting letters of Mr. G. H. Steele and Mr. A. R. Dingley, are we not tending to wrap the "acute ear" and its treatment in too much mystery, thereby confusing and frightening the average G.P.?

As a G.P. who has seen a goodly number of patients—adults and children—with "acute ear" infection during the last four years, I consider that the history—how sudden the onset, the severity of the pain, when the pain was first noticed—in conjunction with the general systemic disturbance, temperature, appearance of the patient, etc., is extremely important before proceeding to the actual inspection of both ears and the throat. A little time taken over this will often gain a child's confidence and make him more co-operative. We all know the difficulty there can be in giving an opinion on an ear in a wriggling, howling urchin, with a small meatus partially blocked by a little wax and epithelium. This should be gently syringed away rather than removed by a wax hook, so that an adequate view of the drum-head can be had. I have at various times postponed the examination till such time as a whiff of ethyl chloride could be given to the child, and the ear condition evaluated. Previous preparation should always be made for a myringotomy, which can be carried out there and then if required. It is my firm opinion that if there is the slightest suspicion of bulging of the drum-head a wide paracentesis should be performed as soon as is convenient and sulphonamides administered. If careful aural toilet be done by someone adequately trained and experienced 99% of these ears will clear up quickly and easily.

The subacute or catarrhal otitis media with an injected drum-head, which so frequently "clears up" under sulphonamide therapy, clears up just as well with aspirin and menthol inhalations. It is in those whose temperature has been crashed down by sulphonamides, whose pain has gone, but in whose middle ears there was pus, that one so frequently finds some time afterwards impaired hearing, some general vague malaise, and a drum-head which has not regained its normal lustre and appearance, due to purulent residue left behind without drainage. What a dramatic improvement takes place when the drum-heads of these are incised and free drainage given! One wonders whether there will not be many more adults in ten to twenty years' time with sclerosed ossicles and impaired hearing, definitely ascribable to sulphonamide therapy without drainage.

I would reiterate my experience and say, Do not temporize, but do an adequate paracentesis, and then start the sulphonamides in doses sufficiently large to be effective.—I am, etc.,

Pinner Green

S. H. CURRIE.

SIR.—Mr. A. R. Dingley, in his instructive article on some dangers of sulphonamides in ear infections (June 3, p. 747), quotes a case of pneumococcal meningitis complicating a middle-ear infection in which, he states, operation (mastoidectomy) was performed "too late to save the boy's life." It would have been interesting to have had the C.S.F. findings in this case.

I believe it is still the practice for aural surgeons to operate on these cases, but while I am not aware that much success can be claimed for mastoid drainage in well-established cases of pneumococcal meningitis, almost phenomenal cures have been obtained by sulphonamide therapy even where mastoid drainage was omitted. Mastoid drainage appears to be indicated in cases of localized subdural abscess, but I suggest that in very ill patients with a more generalized meningitis the preferable treatment is sulphonamide therapy with possibly mastoidectomy when the patient's condition permits.

Though one may doubt the wisdom of subjecting these cases while critically ill to a major operation, sulphonamides should never replace myringotomy where it is indicated in the treatment of any case of otitis media.—I am, etc.,

Stockport.

L. A. QUIRK.

Ether and the Oxford-Vaporizer

SIR.—Prof. R. R. Macintosh, in his reply to my letter, has sought to minimize the incidence of vomiting after the administration of ether through the Oxford vaporizer, disclosed by the report of Drs. Mushin and Wood, by claiming that the post-operative observation of the cases recorded was more meticulous than is usual. Such careful recording of facts is what we have come to expect in reports emanating from his department at Oxford; I had already made due allowance for this. Nevertheless, of the 66 patients, in the series of 89, who vomited, 41 had one to three bouts of vomiting and 25 had over four bouts of vomiting; I cannot think that any great clinical acumen was required to record these facts, nor do I suppose that any of the patients were in any doubt as to their unhappy condition!

Such an incidence of post-operative vomiting is neither more nor less than one expects after ether, and, I claim, fully supports the main contention of my letter that, contrary to the over-enthusiastic reports of users of the Oxford vaporizer, the ill effects of ether upon the patient, of which vomiting is but one example, are not materially lessened by the use of the vaporizer.

Dr. A. D. H. Simpson's letter reads as strangely to me as, he states, did mine to him. He imputes to me words I did not write and meanings I did not imply. I did not reveal the truth that the vaporizer delivers ether; I deplored the fact that it does so. I did not question that ether was the agent employed in the experiment, neither did I mention the concentration of ether vapour in the inspired mixture or its relation to the position of the tap. May I point out to Dr. Simpson that while ether remains the yardstick against which other agents are measured for safety it also remains the example of most that is undesirable in an anaesthetic agent in assessing

the merits or demerits of newer agents. I venture to predict that if any new anaesthetic agent, possessing a fraction of the disadvantages recognized and accepted in ether, were introduced to-day it would, if I may use such an expression, be "thrown out on its ear" after the shortest of trials. The safety of an anaesthetic agent, always excepting chloroform, is, and always will be, directly proportional to the skill and experience of the administrator. In proper hands cyclopropane, divinyl ether, trichlorethylene, and pentothal are as safe as ether, and allow any operation to be performed with a minimum of discomfort and ill effect to the patient.—I am, etc.,

Bournemouth.

S. F. DURRANS.

Prevention of Industrial Dermatitis

SIR,—No one with experience of skin cleansing after contact with cutting oils, grease, and paraffin by means both of my neutral sulphonated castor-oil mixture and of barrier creams can possibly agree with Dr. L. B. Bourne (July 8, p. 57) that just as much co-operation is demanded from the worker in the former as in the latter method. All workers desire to wash on ceasing work, and the method I advocate provides the means of so doing rapidly without the use of soap, which too often in these days is not available. Dr. Bourne's supposition that the factories in my medical charge have unusually good washing facilities is erroneous. In some sections, of necessity, only a bucket of cold water is available without soap or towel, but the results of using the skin-cleansing mixture in such case are equally as good as where proper washing places exist. Dr. Bourne rightly stresses the necessity for the selection of workers, protection by machine shields and protective clothing, inspection of the skin, and cleanliness. These are the A B C of preventive methods, but the first cannot be adequately enforced under war conditions of labour, while the last is impossible with soap and water in machine shops, but is perfectly achieved in a minute or two by the method I use, and I suggest that Dr. Bourne retain an open mind until he himself has seen its results. He can obtain my mixture from Messrs. Reynolds and Branson, 13, Briggate, Leeds, 1, together with instructions for its use.—I am, etc.,

N. HOWARD MUMMERY,
Medical Officer, Aircraft Factory.

Timing of Schäfer's Method

SIR,—I must disagree with Dr. Chapman's reasoning (July 8, p. 57) in his preference for the timing of Schäfer's method given in the *R.A.M.C. Training*, 1935. Most surgeons in the St. John Ambulance Brigade have taught their classes—quite rightly in my opinion—that the mechanics of artificial respiration by Schäfer's method are exactly the reverse of normal respiration, in that normal inspiration is an active muscular process, while artificial inspiration is passive, depending entirely on the natural elasticity of the diaphragm and abdominal contents after the pressure of the hands is released for the entry of air into the thorax. Similarly, normal expiration is a passive act while artificial expiration is the active part of the process.

The mechanics of the act being thus reversed, it seems only reasonable that the timing equally should be reversed, so that the passive part of the cycle in each instance should be the longer. This, as Dr. Chapman points out, is the method adopted by both the St. John textbook and the Royal Life Saving Society.

Eve's rocking method in my opinion is not comparable, as the up-and-down movement of the diaphragm and abdominal viscera by gravity makes both inspiration and expiration into active processes.—I am, etc.,

Rochdale.

A. M. MCMASTER.

Vitamin B Deficiency in Allergic Patients

SIR,—I have read with particular interest the excellent article by J. G. McSorley and L. S. P. Davidson in your May 27 issue (p. 714), which has just arrived. In my recently reported studies of food allergy I have had numerous occasions to combat a deficiency of the "unknown liver factors" of the vitamin B complex. The early symptoms of such deficiency have been

nervousness, anorexia, tiredness, with weakness and tachycardia in some. The quantity of liver extract (Lederle) needed to maintain these patients is frequently much larger than doses suggested in the package circulars—as much as 12 caps daily of the powdered preparation or 6.5 c.cm. of "parenteral" fluid.

A number of patients with allergic sensitivity to one or other ingredient in these mixtures (proteins of beef and pork, orange cocoa, vanillin) have been encountered. Attempts at desensitization in such cases are unrewarding and expensive, but I have found that the B deficiency in these patients can be perfectly met with baker's yeast, provided a sufficient dosage is prescribed. A few patients do well with only one and a half cakes Fleischmann's standard product daily; the others must have from four to seven cakes daily for complete relief of the symptoms of B deficiency.

I have not yet seen a patient who is sensitive to both liver extract and yeast; but one patient highly sensitive to yeast fortunately not sensitive to beef or pork, taking daily 6.5 c.cm. of the parenteral preparation (Lederle) by mouth. It is important in some persons to begin treatment with yeast with small quantities, say one-half cake, crushed in some beverage, and increase this gradually. Large doses taken at first often cause unpleasant gas formation and belching.—I am, etc.,

ARTHUR F. COCA, M.D.,
Medical Director, Lederle Laboratories.
New York.

Gastric Ulcer with Hyperpiesia

SIR,—I wish to report a rather unusual case of gastric ulcer. I was called in to see the patient for the first time on Dec. 28, 1940, during heavy blitzes in Liverpool. He had had a very severe haematemesis followed in due course by melaena. He was kept in bed on sips of cold water and hypodermic injections of morphine for two days. This was replaced by milk diet until melaena cleared up, and he was then put on a normal gastric ulcer regime—an iron preparation in tablet form and injections of a liver extract.

He gave a history of gastro-enterostomy in 1933 at the age of 48 for pyloric obstruction, operation revealing a large pyloric ulcer. An interesting point is that his brother had partial gastrectomy for a similar condition at the age of 48. My patient, a well-nourished man aged 55, had had no gastric symptoms since his operation 7 years previously. He was x-rayed after his attack, and the radiologist reported a healing gastric ulcer at junction of middle and upper thirds of lesser curvature of the stomach, with hypotonic stomach. The surgeon wished to perform partial gastrectomy, but the patient wished to continue with medical treatment. He remained on gastric ulcer diet and the tablets and injections, with complete clinical recovery.

He returned to his normal habits—moderate smoker, occasional glass of beer and no restrictions of diet, and I did not see him again until Jan. 17, 1943, when he complained of dyspnoea on exertion, dizziness, and headaches. On examination his blood pressure was 210/110, and after treatment with phenobarbitone and theobromine tablets, one morning and night, his symptoms improved, but B.P. only dropped to 190/100 by Feb. 7, 1943. He remained free from symptoms until March 23, 1943, when he had another attack of melaena, and his B.P. dropped to 150/80. With general care he improved until Sept. 19, 1943, when his B.P. had again risen to 210/115, where it remained until June 8, 1944, when he had another attack of melaena, which continued until his B.P. fell to 150/85. He is at present on the iron tablets, the injections of liver extract, and plain diet.

It is rather remarkable that his gastric ulcer, the cause of his haemorrhages, has given rise to no gastric symptoms. His haemorrhages have all been related to periods of overstrain and mental stress, factors in a hyperpiesic likely to cause cerebral haemorrhages. I feel that his ulcer is acting as a "safety valve," and suggest that this gastric ulcer was produced by local devitalization of stomach mucosa due to thrombosis of a small gastric artery which was probably arterio-sclerotic. This would account for the ulcer being symptomless. The artery lying at the base of the ulcer crater bursts at periods of mental strain, and bleeding continues until his blood pressure has dropped to 150/110—about right for his age. Under these circumstances I consider that alkalis are not indicated in this type of case, and all efforts should be concentrated on lowering the blood pressure by drugs and diet.—I am, etc.,

Liverpool.

RICHARD H. BRACEY.

Progesterone

SIR—I have followed with amused interest the correspondence between Dr Walter Calvert and Mr Wilson Clyne on the action of progesterone during pregnancy. May I point out that this theory was so far as I am aware, first published by Mr R. Christie Brown in the *Journal of Obstetrics and Gynaecology of the British Empire* autumn 1932 page 596—am, etc.

London W 1

RICHARD SANDS M.R.C.O.G.

Chemoprophylaxis of Gonorrhoea

SIR—Your reviewer, in his comments on Dr Herrold's book, represented that American author as being opposed to the prophylactic use of sulphonamides. In my letter (June 24, p. 855) I pointed out that Herrold recommended that the exposed individual should receive sulphonamides prophylactically from his doctor. Your reviewer now discloses (July 8, p. 57) that it is he and not Herrold who objects to chemoprophylaxis, and he goes on to make the extraordinary suggestion that administration of 6 g. of a sulphonamide on the day following exposure is likely to lead to the sensitization of large numbers of individuals.

There is much yet to be learned about sulphonamide sensitization but it is generally assumed that it usually occurs towards the end of a course of treatment extending over a number of days. If there is evidence that one day of treatment (or of prophylaxis) has been ever or often the cause of sensitization, I hope your reviewer will tell us about it. It is the therapeutic and not the prophylactic use of sulphonamides that is likely to result in sensitization.

Theoretically, it is possible that chemoprophylaxis (like chemotherapy) may be responsible for latent gonorrhoea, but adequate dosage is believed by many to be the best safeguard against this danger. Surely no one will regard as inadequate a prophylactic dosage of 6 g., having in mind that the total amount of drug required to cure an established infection is far greater than that needed to deal with the relatively small initial inoculum.

My final observation is one of regret that your reviewer has so patently not observed that impartiality which readers are entitled to expect in the columns of the *Journal*—I am, etc.,

W. J. BAKE, Ltd.
Dagenham, Ess.

ROBERT FORGAN, M.D., D.P.H.

Service Medicine

SIR—Service medicine has been assessed both by junior medical officers and by others of higher rank, like Air Cdre Cade and Conybeare (April 22, p. 574). The junior officers have in most instances, preferred to remain anonymous, and this significant fact is, I suggest, quite explicable when the last paragraph of the letter from Air Cdre Cade and Conybeare is read: "It has been our experience that in the rare cases in which we have heard this complaint from medical officers the officer is either lazy or incompetent or else he is one of those disgruntled persons who is primarily interested in his own comfort and career rather than his contribution to the war effort."

Junior officers seldom criticize because they fear that this type of judgement will be made of them by those senior officers who are responsible for appointments and promotion. This fear may be unfounded, but that it is widespread is doubted only by those whose high rank prevents them hearing the day to day talk in mess or wardroom. The junior officer is convinced that criticism does not pay, and the letter from the Air Commodore will do nothing to destroy this—possibly unfounded—conviction—I am, etc.,

Wolverhampton

G CAMPBELL

SIR—A fact not so far noted is that a system which gives reasonable results in a closed disciplined community of picked lives may not be suited to dealing with a mixed populace. Even so nothing like the following would, I venture to think, be likely to occur under private practice conditions.

A slim married W.A.A.F., aged 22, paraded for routine medical examination on reposting. For reasons best known

to herself the young woman M.O. told her, despite her protests, that she was pregnant and deferred her one month. After five weeks the patient, having started a normal period, paraded again. A fresh woman M.O. looked at her card and, despite further protest, sent her to bed for two weeks in hospital as a 'threatened abortion'. In due course the patient was discharged from the Service (with all the extra coupons, etc.) as pregnant. After a further menstrual period she came to me at an alleged 34 months, utterly mystified, with no signs or symptoms of pregnancy and a negative Z/A—I am, etc.,

M.B. B.Ch.

Spanish Medicine

SIR—Prof. Dillon in writing of misunderstandings of Spanish medicine (July 15, p. 96) has left some misunderstandings. He writes: "The clear truth is that medical advances are quite independent of political or ecclesiastical regime." They depend largely on the wealth and education of the country concerned. Spain is poor and her people have had few opportunities of secondary and university education, because she has been ruled for 100 years by an oligarchy of more or less corrupt politicians. Perhaps therefore, he will tell us at which period in her history Spain showed any eminence in medicine or science and what were the reasons for that eminence. The names of Spaniards who made important contributions, to medicine or science would also be helpful to the historian.

It should be remembered that for many centuries Spain was a very rich country and for long the richest in the world, and that her educational institutions were particularly numerous and well endowed. There are or were, no fewer than thirteen ancient universities in the peninsula without counting post-Renaissance foundations—I am, etc.,

The Athenaeum, London S.W. 1

CHARLES SINGER

The Services

Acting Surg. Cmdr E. G. Brewis and Surg. Lieut. Cmdrs A. S. Pearson and D. M. Dean, R.N.V.R., have been awarded the R.N.V.R. Officers' Decoration.

Temp. Surg. Lieuts H. P. Lesselbaum and R. R. Wethered, R.N.V.R., have been mentioned in despatches for good services in saving lives and valuable material in a heavy air raid on Bari.

CASUALTIES IN THE MEDICAL SERVICES

Surg. Lieut. Myles Clayton Cross, R.N.V.R., who was posted missing, presumed killed, at the end of last year, was educated at Lancing at Trinity College, Cambridge, and at Guy's Hospital. He qualified M.R.C.S. L.R.C.P. in 1941 and completed his M.B. B.Ch. in 1942, he held house appointments at Guy's and later in the Emergency Medical Service. In September, 1942, he was accepted for the R.N.V.R. and saw service in the North Africa landings, and at Panellaria, Sicily, and Salerno.

Wounded—War Subs. Capt. B. E. Camus and J. P. Turner, R.A.M.C.

Missing, now presumed killed in action at sea—Maj. R. Edwards, R.A.M.C.

Killed as the result of an accident—Col. W. J. S. Ingram, M.C., I.M.S.

Died of wounds—War Subs. Capt. C. W. Hamillon, R.A.M.C.

DEATHS IN THE SERVICES

Lieut. Col. HERBERT HENRY GEORGE KNAPP, M.D., D.T.M.&H., I.M.S. (ret.) died on July 3 at Bournemouth in his 75th year. He was educated at Oxford and at St. Mary's Hospital, obtained honours in the Oxford B.A., took the B.M., Ch.B. in 1896 and the D.M. in 1899. He passed the D.T.M. and the D.T.M.&H. Camb. in 1913. He first served in South Africa from 1897 to 1901 as plague medical officer and as civil surgeon R.A.M.C. In 1902 he entered the I.M.S. and rose steadily to reach the rank of lieutenant-col. in 1921. He was awarded the Queen's medal with four clasps for his active service in South Africa in 1900-1. He entered the civil department in the Bombay Presidency, served in the Jail Department, and was later promoted to be Inspector General of Prisons in Burma. Among other interests he became a Fellow of the Royal Anthropological Institute.

Lieut.-Col. GEORGE EDWARD STEWART, M.B., C.M., F.R.C.S.Ed., I.M.S. (ret.), died on Nov. 29, 1943, in Jersey, aged 70. He was born at Hamilton, Ontario, in 1873 and was educated at Victoria College, Jersey, and at Edinburgh University, where he qualified in 1898 with the M.B., C.M. He subsequently took the F.R.C.S.Ed. and the D.T.M. of Liverpool in 1908. He entered the I.M.S. in 1898 and rose to be lieut.-col. on the selected list by 1923, but had to retire under the age rules before attaining the administrative grade. He saw active service in 1900 in China, in 1901 in Mekran, in 1908-10 in Somaliland, and gained medals for each campaign. He served throughout the war of 1914-18 in Waziristan and Mesopotamia, and was mentioned in dispatches. After his retirement he went to live once more in Jersey, and enemy action was doubtless the cause of the delay in the news of his death reaching this country.

Obituary

SIR WILLIAM LISTER, K.C.M.G., K.C.V.O.,
M.D., F.R.C.S.

Sir William Lister, Consulting Surgeon Oculist to the King since 1926, who died at his home in High Wycombe, Buckinghamshire, on July 7, had been a leading figure among the ophthalmologists of London. He taught a long succession of students at Moorfields Eye Hospital and the London Hospital, and did notable work during the last war as consultant to the British Expeditionary Force.

William Tindall Lister was born on Nov. 4, 1868, the youngest son of Arthur Lister, F.R.S., botanist and authority on the myceliozoa, and was a nephew of the great Lord Lister. Like his brother, J. J. Lister, F.R.S., zoologist and Fellow of St. John's College, who died in 1927, William Lister went to Cambridge University, graduating B.A. from Trinity College in the Natural Sciences Tripos of 1889. After his clinical course in London at University College Hospital he obtained the M.B., B.Ch. degrees at Cambridge in 1892 and the F.R.C.S. diploma in 1895; he proceeded M.A. and M.D. in 1922. Diseases of the eye attracted him from the time when he held resident house appointments, and it was not long before his judgment and

(Press Portrait Bureau)

operative skill became recognized by election to the posts of assistant surgeon to the Central London Ophthalmic Hospital and ophthalmic surgeon to the Hospital for Sick Children. After a period as curator of the pathological museum at Moorfields he was elected to the visiting staff there. When war broke out in 1914 Lister had been ophthalmic surgeon to the London Hospital for some time; he was then invited to take charge of the ophthalmic arrangements for the Expeditionary Force in France, and worked and planned there until 1918 with the rank of colonel, A.M.S. In 1918 he gave a Hunterian Lecture before the Royal College of Surgeons, recording some of his large war experience of injuries of the eyes by gunshot fire and mustard gas. He continued his interest in the welfare of officers and men as ophthalmic consultant to Queen Alexandra's Military Hospital after the war. He was created C.M.G. in 1916 and K.C.M.G. in 1919 for his work during the last war, and K.C.V.O. in 1934 in recognition of his services to the King and the Royal Household.

Mr. CHARLES GOULDEN has written an appreciation from which he allows us to quote:

I first met Sir William Lister in July, 1904, when I became a junior clinical assistant to Mr. William Lang at Moorfields. Lister had the desk, in the out-patient department, next to Lang's. He was always very friendly and found time to explain anything I might ask him. This was the more generous as he had little assistance and he found a large clinic somewhat bewildering. He was not a rapid worker and he set himself such a high standard that by the

end of the morning's work he was exhausted. He had been an assistant surgeon in 1904, but in 1905 he found the work too much for him and, being by no means robust, he resigned. He had elected ophthalmic surgeon to the London Hospital in 1903, was not surprising that he found he could not run two large clinics. These and two teaching schools were more than he could manage. It was a great pity he had to retire from Moorfields at the time the school was undergoing development and rejuvenation, as he was a capital clinical teacher. Before his election to the staff he served for five years as the pathologist and curator of the museum and he had cultivated a beautiful technique in the cutting of sections and the mounting of specimens. He was a highly expert photographer and his photomicrography was of the highest order.

In 1914 he undertook the arduous task of organizing the ophthalmic service of the British Armies in France. By his persistence ultimately overcame all difficulties and set up a most successful organization whereby not only was there an ophthalmic consultant available for each Army but surgical aid was obtainable at certain casualty clearing stations. The ophthalmic work was centralized at each base so that cases were admitted to one hospital where a group of surgeons worked. At each of these hospitals there was an out-patient department for the treatment of minor complaints; there was also a complete spectacle service whereby a man might have his spectacles ordered and supplied in perhaps half an hour. This was a great triumph, and it was achieved in the face of much opposition. Lister in conjunction with the late J. F. Cunningham acted as a roving consultant, visiting all the bases and forwarding regularly as well as being on call when a second opinion or aid was needed.

In 1918 Sir William resigned from the London Hospital so that he might give more time to postgraduate teaching, and in 1919 was re-elected to the staff at Moorfields and entered with his customary enthusiasm on the work for which he had great talent—training of postgraduates in ophthalmology by clinical teaching in the out-patient department. He also did his share in the giving of lectures. He was able to make use of his extensive collection of specimens, drawings, and photographs, many of which he had been too shy to publish. By his generosity a small clinical theatre was built at Moorfields, in which a case of special interest appearing in the clinic might be demonstrated. He made many other gifts at Moorfields.

Lister excelled in all branches of ophthalmology. He had had prolonged training in clinical work, and a long period as a pathologist. He was a good operator, although apt to be very conservative. His opinion was frequently sought by his colleagues, and mention must be made of his efforts to improve instruments in common use by that of an ophthalmic surgeon. Lister was a lovable man and full of fun; he had great charm of manner and was a delightful host. He had a great sense of duty, and, having considerable wealth, looked upon it as a trust whereby he might assist the less fortunate. Many have reason to remember his kindness and generosity.

JOHN PATRICK, F.R.C.S.Ed., F.R.F.P.S.GLAS.

The sudden passing of Mr. John Patrick, for many years consulting surgeon in Glasgow, came as a shock to many. His immediate friends had noticed evidences of failing health over the past year or more in one who was formerly virile and full of energy. This culminated a few months ago in a prolonged residence in a nursing home because of a condition of heart-block. He so far recovered as to be able to move about slowly and later to proceed for a short holiday to Arran where he had for so many years spent his various periods of relaxation from work. Though far from well on his return he elected to keep going about, and to resume some of his lighter duties. His sudden fatal seizure brought to an end a very useful and busy life, in which he never spared himself in helping others in their time of trouble. He leaves behind him a splendid record of work well done, and will be much missed by his many friends in this neighbourhood and elsewhere.

His father, Dr. William Patrick, was a well-known and highly respected practitioner with a busy practice in an industrial part of Glasgow. John was born in the Bridgeton area, and was educated at the Glasgow High School, from which he proceeded to Glasgow University. He graduated M.A. there in 1889, and M.B., C.M. in 1893. After a period of residence in the Royal Infirmary with the late Sir David C. McVail he spent a year as resident surgeon in the wards of the late Sir William MacEwen in the Western Infirmary. Here he gained the grounding in aseptic surgery and the wide clinical experience on which his after-life was based. Later he was outdoor house-physician at the Glasgow Maternity Hospital, from which he proceeded to Vienna for further surgical study before joining his father in his extensive

practice. He early was appointed to the visiting staff of the Royal Infirmary, passing in due course through the various stages to the post of assistant surgeon. By this time he had qualified for, and obtained, the Fellowship of the Royal College of Surgeons of Edinburgh (1908) and the Fellowship of the Royal Faculty of Physicians and Surgeons of Glasgow (1909). The war came and he was attached to the 4th Scottish General Hospital as a surgeon, proceeding over-seas in 1916 to Salonika as a surgical specialist with the 38th General Hospital. He remained there till the end of hostilities, latterly serving as consulting surgeon with the rank of lieutenant-colonel, and was awarded the Grecian Order of Military Merit for his services.

Shortly after his return to Glasgow he was promoted and became visiting surgeon to the Royal Infirmary, where his good work and his value as a teacher were soon recognized by the students. Patrick had the gifts of facile speech and lucid illustration, which soon gained for him large and enthusiastic classes. Here he gloried in his work till his period of service came to an end, and he was appointed to the honorary consulting staff. During his service as visiting surgeon he held the post of lecturer-examiner in clinical surgery in Glasgow University, and also an examinership in surgery for the licence of the Scottish triple qualification.

He was an enthusiastic member of the Association of Surgeons of Great Britain and Ireland, regularly attending meetings all over this country and abroad, and so enlarging and enhancing his experience by comparing notes with surgeons from all quarters. He had a ready pen as well as speech, and made good use of this gift in many contributions to the surgical literature of his time. For many years also he acted as surgical editor of the *Glasgow Medical Journal* with great acceptance, his literary knowledge and thoroughness specially fitting him for work of this kind. He was always an enthusiastic member of the British Medical Association, being at one time a member of the Scottish Committee and of its Central Council. His literary capacity was recognized by that body, who utilized his services as a local correspondent for this area for many years. The emergencies of the present war brought him into harness again, and he resumed his surgical editorship of the *Glasgow Medical Journal*, as well as resuming his work as a clinical teacher one or two days weekly till his health broke down. He thoroughly enjoyed being back among the students again.

Outside of his medical work Patrick was interested in the arts and especially in music, from which he derived great enjoyment and relaxation. Right up to the end he kept up his interest in games and sport generally. Throughout a busy life he kept himself fit by his habit, whenever possible, of having his regular round of golf with his friends on a Saturday, his favourite resort being the old course at Troon. He is survived by his widow, one daughter, and four sons—three of whom are on service over-seas, two of them being with the R.A.M.C.—to all of whom we extend our deep sympathy in their sudden great bereavement.

J. H.

WILFRED J. HADLEY, M.D., F.R.C.P.

Dr. Wilfred Hadley, who died in retirement at his home in Reigate on July 6 aged 82, was a consulting physician of the old school, and for many years served on the visiting staffs of the London Hospital and the Victoria Park Chest Hospital. He had a high reputation as a teacher at the bedside, with a remarkable gift for perceiving and demonstrating in clear language the essential features of a case.

Wilfred James Hadley was born at Gloucester on March 28, 1862, and after schooldays at Taunton went to study medicine, first in London and then at Newcastle-upon-Tyne, graduating M.B. of the University of Durham with first place in the honours list in 1886, and M.D. (with gold medal) in 1893. His clinical apprenticeship was partly at the London Hospital, and after graduation he went to Göttingen University for a time. He held a succession of house appointments at the London Hospital after qualifying in 1883, and then became pathologist and lecturer on medical bacteriology and curator of the museum there; he began his long connexion with the Victoria Park Hospital as pathologist. Dr. Hadley obtained the F.R.C.S. in 1887, the M.R.C.P. in 1890, and was elected a Fellow of the Royal College of Physicians in 1899, representing the College as examiner in medicine for the English Conjoint Board in

1908-12. He was part author with Sir Andrew Clark and Dr. Arnold Chaplin of a book on *Fibroid Diseases of the Lung*, which ranked high in medical literature, and of a small book, *Nursing: General Medical and Surgical*, which was published in 1901 and reached a second edition in 1907; he also wrote on diseases of the respiratory system for the *Medical Annual*, and contributed a few papers to medical and scientific journals. During the last war he served with the rank of captain, R.A.M.C.(T.), and was physician to the Endsleigh Palace and Palace Green Hospitals for Officers. On retirement from the full staff of the London Hospital and the Victoria Park Hospital he was elected consulting physician to each. His daughter, Dr. Margaret Hadley Jackson, who held a number of house posts at "The London," is in practice at Crediton in partnership with Dr. H. F. L. Hugo and her husband, Dr. L. N. Jackson.

T. W. WADSWORTH, M.D., F.R.C.P.

Tom Watson Wadsworth, who died on June 23, left behind, in his native city, a fine record of work faithfully performed. From his undergraduate days his ambition was to be a consultant physician, and four years' service during the first great war hardly interrupted his studies, for he became a member of the Royal College of Physicians while in the R.A.M.C. In 1919 he was elected to the honorary staff of the Liverpool Stanley Hospital and later to the Hospital for Diseases of the Chest and the Providence Hospital, St. Helens. In 1920 he was appointed visiting physician to Walton Hospital, and in this position he did pioneer work, as he was given charge of beds and was probably the first to work under these conditions in a Poor Law hospital. For many years he personally examined every medical case admitted. He was a most careful worker, seldom making a spot diagnosis, but preferring to reach his conclusions after a complete routine examination. Honesty was one of his characteristics; whatever he undertook to do was scrupulously carried out. He did not set an extravagant value on his services, and he always took particular care to give full value for fees paid to him. He could not bear to accept from a patient more than he could afford to pay.

He was an active member of the B.M.A. He had been chairman of the Liverpool Division and had represented it at the Annual Representative Meeting for many years. He regarded himself as a typical Englishman and he took great pride in making his conduct conform to this ideal. This was associated with a dislike of ostentation or display of any kind that amounted to a fault. The place he held in the esteem of the local profession was indicated by the number of doctors or members of their families who were among his patients. An interest in physiology aroused during his student days remained with him throughout life, and for many years he lectured on applied physiology in the University of Liverpool. Outside his profession his chief interests were in the history of science and in various forms of handicraft. He had hoped for a period of retirement when he would be able to indulge his tastes, but he felt it his duty to contribute to the war effort, and he continued to attend some of his hospitals after his retirement from private practice. Towards the end he came to realize that if his life was to be prolonged he would have to limit his activities very strictly. This would have been intolerable to one of his active temperament, and he refused to alter his way of living. His marriage was a particularly happy one, and much sympathy is felt for his widow. In Walton, the hospital to which he devoted so much of the work of his life, he is remembered with affection.

H. H. M.

The death is announced of Dr. EDWARD FERDINAND PAGE, who practised at Solihull, Warwickshire, for many years, and joined the British Medical Association in 1890 immediately after qualifying as L.S.A. He took the M.R.C.S., L.R.C.P., diplomas in 1899 and the M.B., B.Ch. degrees of Birmingham University in 1901, and he held many public appointments in succession to his father. G. C. B. writes: In the passing of Dr. Ferdinand Page we lose a beloved colleague, a man of the old school, who throughout his life carried on the arduous duties of a country practitioner. Only those who do this work know its hardship, but he never grumbled nor thought of the humdrum work that falls to the lot of a country doctor. The daily routine of his practice was, however, leavened by an occasional follow-up of the hounds (a sport he loved), and what little leisure he had was taken up by handicraftsmanship. He was a friend of the late Jordan Lloyd when tuberculous joints were fixed up in elaborate splints, and Page, being the artist in woodwork, perfected these splints for him. Page was a man of sound judgment and his knowledge of psychological

Air Transport and Convection of Disease—Mr WILLINK said on July 13 that he was unaware that air transport at present caused diffusion of disease. The risk that infectious disease could be thus conveyed from one country to another was recognized and was the subject of an international sanitary convention regarding aerial navigation, which provided for safeguards. Every precaution was being taken against the incursion of epidemic disease into this country by this means.

Medical Examination of Irish Workers—Mr PETERLIN inquired on July 12 whether men and women coming from Ireland to England, Scotland, or Wales to work were medically examined at the ports on arrival. Miss HORSBRIGHT said they were not, except that such examinations had been temporarily carried out on one or two occasions when a special risk of the possible importation of major infectious disease had appeared.

EPIDEMIOLOGICAL NOTIS

Discussion of Table

In England and Wales during the week the incidence of infectious diseases fell, the only exception being a rise of 106 in the notifications of acute pneumonia. Dysentery had 66 fewer notifications than last week, diphtheria 55, whooping cough 42, and measles 35.

There was a slight fall in the notifications of diphtheria in most areas and no large fluctuations were recorded. Cheshire reported 57 fewer cases of whooping-cough than last week, Surrey 57, and London 55. The largest falls in measles were Northumberland with 75 fewer cases, and Southampton with 44 fewer, but in Lancashire the total went up by 79.

The notifications of dysentery dropped from 201 to 135, the lowest weekly total recorded this year. The largest returns were those of Surrey 22, Yorks West Riding 13, Lancashire 12, Glamorganshire 12, London 11, Sussex 11.

In Scotland 115 fewer cases of measles were reported. The notifications of this disease have fallen by two thirds during the past month.

In Eire there was a rise of almost 100% in the notifications of measles owing to the outbreak in Clure, Ennis UD, where 102 cases were reported during the week.

Diphtheria

There was a small general fall in the incidence of diphtheria in England and Wales during the week. The disease has been at a relatively very low level for the past six weeks, and the 432 notifications are the lowest ever recorded. The incidence is higher in the north than elsewhere, during the week reviewed the two counties of Lancashire and Yorks West Riding had 67 and 70 of the total notifications. It appears that the campaign for immunization has now successfully lowered the incidence of this disease. Although there could still be a great improvement, a comparison of the notifications in the first two quarters of the year is

Weeks	1937	1938	1939	1940	1941	1942	1943	1944	1944 as % of Average of 1937-41
1-13	14 973	20 941	14 888	9 199	14 533	11 658	10 799	9 008	69
14-26	12 472	13 245	10 167	9 022	11 614	8 911	8 556	6 973	62

The fatality rate has also fallen. The deaths per 1,000 notifications in the great towns during the first twenty six weeks of 1944 were only 30, compared with 58, 45, and 42 for the first six months of 1941-3. The diagnostic error has increased during the past years, judged from some London hospitals' experience. This increase may account for a part of the reduced mortality, but it would also mean that the reduction in incidence is greater than indicated above.

Notification of Measles and Whooping-cough in Scotland

It has been pointed out by a reader that measles and whooping-cough are not notifiable diseases in Scotland. The returns for these diseases issued by the Department of Health for Scotland, and printed each week in our epidemiological table, are based on (a) admissions to hospital, (b) reports of absenteeism from school teachers and attendance officers, (c) information from health visitors, medical officers of the child welfare department, (d) information from sanitary inspectors, and (e) intimations from children's homes etc. The figures are, therefore, an index of the general incidence but cannot be taken as statistically accurate, and are probably, in general, as underestimate.

Week Ending July 8

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,390, whooping cough 2,325, diphtheria 425, measles 2,571, acute pneumonia 539, cerebrospinal fever 45, dysentery 132, paratyphoid 8, typhoid 3.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 1.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland

Figures of Births and Deaths and of the 1000 live births and deaths, are for (a) The 126 great towns (b) London (administrative county) The 13 principal towns in Eire (e)

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation, homes and other movements of population birth and death rates for Northern Ireland are no longer available.

Medical News

The attention of readers is drawn to the notice in our advertisement columns of vacancies for professors in the Departments of Pathology, Physiology, and Surgery in the Royal Faculty of Medicine, Baghdad, Iraq. Candidates should be available for appointment as from Oct. 1, 1944. The salary payable in Iraqi dinars is equivalent to £1,800 a year, in addition to which there would be a monthly cost-of-living allowance of £24. Candidates should have had at least eight years' teaching experience in a British university or other recognized medical school. Applications should be addressed to the British Council, 3, Hanover Street, London, W.1, and should include full particulars of past experience and appointments held, together with three copies each of three recent testimonials or the names of three referees.

A meeting of the Council of the Medical Superintendents' Society will be held at the Queen's Hotel, Birmingham, on Friday, July 28, at 2.30 p.m., and Saturday, July 29, at 10 a.m.

The Acting Editor of *Public Health*, the official organ of the Society of Medical Officers of Health, regrets that the July issue, and possibly subsequent ones, will be delayed, the printers having received severe damage from enemy action.

A reception was held at the Dorchester Hotel, London, on July 8 to mark the twentieth anniversary of the formation of the Society for Cultural Relations with the U.S.S.R. Since its inception this society has arranged for the interchange of information between the two countries and also for personal contact between many scientists, scholars, and artists. In 1934 it arranged for a number of doctors from Great Britain to attend the Conference of the International League against Rheumatism held in Moscow, and many doctors have toured the Soviet Union under its auspices.

The Ministry of Health's Memorandum V. 21 on the subject of tests which it is considered should be applied to V.D. patients before they are regarded as discharged after completion of treatment and observation has now been revised, and copies have been sent to medical officers of Venereal Diseases Treatment Centres. It is thought that the memorandum will also give helpful guidance to medical practitioners who have been appointed by local authorities under the provisions of Circular 2226 to examine and treat patients at their own surgeries, and to those recognized or designated as special practitioners for the purpose of Regulation 33B. Copies are in the hands of medical officers of health for distribution.

The U.S. Office of War Information in a circular dated June 13 mentions a new product from agricultural research laboratories in America. It is a type of cotton bandage fabric that tends to fit and cling better than ordinary gauze and allows greater freedom of movement in bandaged joints. Valuable properties of the new fabric are a high degree of "stretchability" which makes the bandage partly self-fitting so that it conforms to irregular surfaces. It also has enough elasticity to make it flexible and somewhat self-tightening without restricting the circulation of the blood, and a roughened surface which causes layers of bandage to cling together in contrast to the slipperiness of ordinary gauze. The bandage is made by chemically treating ordinary open-weave gauze.

The annual report for 1943 of the Director of Medical Services, Sierra Leone, appears in the abbreviated form which is now usual in the Colonial Medical Service. It shows the difficulties which obtain under war conditions and the endeavours to combat them with a depleted staff, with practically no reliefs. The Director of Medical Services and his officers are to be congratulated on the way they have met the now prolonged emergency. Naturally, large measures have to be postponed until the end of hostilities, and even so urgent a problem as the prevalence of malaria at Freetown and its effects on maritime services must be held up until a satisfactory long-term scheme can be evolved and carried out.

UNRRA's expert commissions on quarantine and on the health problems of displaced persons in Europe have drafted two conventions modifying the International Sanitary Convention, 1924, and the International Sanitary Convention for Aerial Navigation, 1933, and have drawn up minimum international health measures for application to displaced persons. The conventions provide: (1) that UNRRA shall carry out the duties and functions previously performed by the International Office of Public Health, Paris, without prejudice to the future status of that body; (2) that while the system of notification and communication of information referred to in the 1926 and 1933 conventions is to remain in force, Governments signing the new conventions will undertake to transmit such notifications and information to UNRRA together with information on diseases other than those mentioned in the conventions. To deal with this work Dr. Andrew Topping, Director of Health of UNRRA for the European region, has set up an Epidemiological Intelligence Bureau.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to the EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Tuberculous Peritonitis in Adults

Q.—What are the present accepted ways of dealing with tuberculous peritonitis in an adult, and what is the prognosis?

A.—No great advance in the treatment of tuberculous peritonitis has been made in the last few years. The patient should be kept in bed under favourable hygienic conditions. A diet with plenty of vitamins A, C, and D should be prescribed and the bowels kept open. Regular exposure to real or artificial sunlight should be given. X-ray exposures have been recommended, but the results are variable. In women the seat of the primary cause of the peritonitis is frequently found in the Fallopian tubes, and surgical removal of the focus is justified in some cases. In cases in which the abdomen has been opened in error for appendicitis it has been noted that improvement often takes place, and on the strength of this the use of therapeutic pneumoperitoneum has been advocated. Some good results have been reported, and in skilled hands the treatment is without danger.

Bronchiectasis in a Child

Q.—A boy aged 12 suffers from bronchiectasis with frequent haemoptysis. The fingers are much clubbed, and there is a history of bronchopneumonia at the age of 3, after measles. There is also a history of pleurisy. No tubercle bacilli have been found in the sputum. X rays show dense shadows in the region of the middle lobe of the right lung. Lipiodol examination has not yet been made. Is lobectomy a feasible treatment for bronchiectasis at this age? If not, what other line of treatment should be adopted?

A.—In a suitable case lobectomy is undoubtedly the best treatment for bronchiectasis in a child, since the mortality from this operation under the age of 14 is negligible and the results are excellent. The operation can be undertaken only if the disease is localized, and this must be ascertained by careful bronchographic examination of both lungs. If the disease is found to be too extensive for operation, the best treatment will consist of postural drainage and breathing exercises. The investigation and treatment of such a patient may require considerable skill, and it is therefore best carried out at a chest hospital.

Stilboestrol for Leukoplakia Vulvae

Q.—Is there any danger of cancer following the administration of stilboestrol 5 mg. once daily in a woman of 68 who complains of pruritus vulvae with small patches of leukoplakia? After two months, menstruation (not only bleeding but mucous discharge, epithelial cells, etc.) began and fullness of the breasts was observed. The effect on the vulval condition was to cure it. On stopping the stilboestrol for three months the condition (soreness and irritation of the vulva) returned, more mildly than before. Is there any objection to her resuming the treatment?

A.—The answer to the first part of the question is that there is always a danger of cancer following leukoplakia of the vulva. It is also known that most oestrogenic substances, including stilboestrol, are mildly carcinogenic. Carcinoma due to the known carcinogenic substances occurs in man only after a long period of exposure—e.g., many years in tar epithelioma. Whether the combination of a precancerous condition, such as leukoplakia, with the administration of a carcinogenic substance, such as stilboestrol, might precipitate the onset of carcinoma is difficult to determine, and if a carcinoma arose in such circumstances it would be hard to know if it was actually caused by the administration of stilboestrol. Since in the case mentioned in the question the condition has been temporarily cured by stilboestrol, I can see no objection to giving another short course—say, three months—keeping the patient under careful observation and warning her that the subjective symptoms, such as menstruation, may be expected to recur. I should recommend that

use of smaller doses, at any rate at first; 2 mg. a day is often sufficient to control the symptoms. It is believed that this condition may be partly due to a deficiency of vitamin A, and it has also been found that many of these patients have achlorhydria. Dilute hydrochloric acid with meals and vitamin A in large doses may help. I assume that glycosuria and trichomonas vaginitis have both been excluded.

Stubborn Asthma

Q.—A woman patient with asthma does not react to either injections of adrenaline or ephedrine by mouth. None of the usual antispasmodic drugs have any effect. Morphine gr. 1/3 gives relief, but her condition after the injection is alarming. She becomes deeply cyanosed and foams at the mouth. If I do not give morphine she gets no relief.

A.—This is not an uncommon problem and it is sometimes due to the patient's postponing treatment till the attack is well established. The results with adrenaline may be improved by periods of continuous administration, subcutaneously, at the rate of 1 minim a minute for half an hour or so. Inhalation of a 1% solution of adrenaline is also sometimes effective. If adrenaline fails, aminophylline is the drug of choice; it may be given by mouth (up to 9 to 12 gr. daily, starting with a small dose and carefully working up); or intravenously (an ampoule of 0.24 g. in 10 c.c.m., injected very slowly). An intravenous injection of a mercurial diuretic—e.g., inj. mersalyl B.P. 0.5 to 2 c.c.m.—may also be tried. General measures should not be neglected—kapok pillow, sponge-rubber mattress, removal of carpets, hangings, and other dust-producing agencies. Massage and respiratory exercises may be effective, particularly if they are combined with psychological treatment by suggestion and persuasion that the patient can overcome the spasm.

Frigidity after Childbirth

Q.—I have twice recently been consulted by young couples troubled by what might perhaps be termed secondary frigidity. The story is identical in either case. Following the birth of the first child after little more than a year of marriage, there has been no resumption of sexual intercourse on account of the distaste felt by the wife. In both cases the wife, previously eager for and satisfied by intercourse, is now strongly averse to coitus or even to preliminary love play, and is worried by this aversion, which has now lasted for 6 and 9 months respectively. In neither case is there any obvious psychological basis. Both couples are very "happily married." Is this a recognized syndrome? Is there any endocrine or other treatment advisable?

A.—This is a recognized psychological syndrome, and is not endocrinological. The fact that the patient is worried by the aversion to coitus suggests that the real cause is subconscious, and that the patient's attitude to further coitus in the circumstances described is ambivalent. Each case has its psychological background. Not infrequently psycho-analysis reveals that the patient both desires and resents motherhood, and especially the passing from the phase of the idealized bride to the more prosaic mother figure, with the possible resulting danger of losing the man's love. This may be thought more probable with multiple pregnancies, and is, in fact, sometimes the case. At the same time the woman loves the man very much, and is therefore disturbed by the conflict. Contraception, even if 100% reliable, which it is not, is an inadequate answer. Many cases respond to a few talks given by a doctor with some psychological insight. Others require more extensive psychotherapy.

Warts

Q.—For more than a year I have, without much success, been treating my little girl aged 10 for a wart on her knee. The skin of the knee is rather horny and the position of the wart such that it is constantly rubbed by the edges of frocks, coats, etc. I would be glad of suggestions as to treatment.

A.—Allow the wart to grow and then treat with 3% watery solution of formalin, in the following way: The surrounding skin must be protected by vaseline and the solution brought into contact with the wart on cotton-wool, held in forceps or on a stick, for 15 minutes daily.

Peas and Intestinal Flatus

Q.—Why does a diet of peas cause intestinal flatus? How can they be cooked or treated so as to be free from this defect? What gas is evolved in the intestine? What treatment is effective for flatus so caused?

A.—Peas, like beans and lentils, are relatively rich in protein and carbohydrate, but they are not well digested because the food material is enclosed in cells with cellulose walls which resist digestion. Moreover, the cellulose and the associated bulkiness of peas when cooked stimulate peristalsis, so that the chyme is swept into the large intestine before complete digestion has taken place. These disadvantages can be overcome to some extent by prolonged soaking of dried peas, or by the use of pea flour. Usually the flatulence is the result of

fermentation of the undigested carbohydrate of the peas in the large intestine and the release of CO₂, methane, and small amounts of hydrogen. Fermentation of the protein will also give rise to CO₂, together with H₂S and mercaptans, which are evil-smelling compounds. In addition, intestinal gas always contains a fairly high proportion of nitrogen. The only effectual preventive of flatus so caused is to avoid eating peas.

Action of Digitalis

Q.—In discussing the action of digitalis in congestive heart failure, a modern American textbook (Goodman and Gillman—"The Pharmacological Basis of Therapeutics") places prime importance on the direct action of the drug on the heart muscle. Beneficial results are said to be due to increased force of contraction, which together with more complete emptying and filling of the ventricle leads to increased cardiac output. Primary vagal effects are not considered to be important, and the cardiac slowing which occurs is said to be mainly reflex through the vagus as a result of restoration of compensation. Is this teaching in keeping with modern British views?

A.—It is sufficient comment on the views of the book mentioned to point out that, in the whole discussion of the use of digitalis in the treatment of heart disease, the names of Mackenzie and Lewis receive only one passing mention in small type. Nevertheless it is true that modern British views are changing. Mackenzie and Lewis's work led to the conclusion that digitalis was useful only in auricular fibrillation, and then because of its depression of conduction in the bundle of His and of its stimulation of the vagal centre. It is now increasingly realized that digitalis has a beneficial action on heart muscle in congestive failure where there is no disorder of rhythm. Fraenkel's work on strophanthin (*Lancet*, 1935, 2, 1101) emphasized this. He showed the rapid loss of oedema in patients with normal rhythm which followed the administration of strophanthin intravenously.

Vaginal Discharge after Hysterectomy

Q.—A patient who had a hysterectomy for multiple fibroids about four months ago has had a most persistent and offensive vaginal discharge since; there was no evidence of malignancy. The patient's general condition is good. She is on stilboestrol daily. I have tried various remedies, and should be grateful for any suggestions to relieve this condition.

A.—Vaginal discharge after a total hysterectomy is fairly common. If silk has been used to ligature the uterine vessels infection may cause suppuration for a long time. If a large raw area has been left in the pelvis and becomes infected, persistent purulent discharge will result. Sometimes granulations form along the scar in the vaginal vault. These can be cured by cauterization with silver nitrate. If both ovaries were removed it is possible that a trichomonas infection has been lighted up. The case should be investigated along these lines and an accurate diagnosis made. As a general rule it can be said that the prognosis is good and there is no cause for anxiety.

Congenital Deaf-mutism

Q.—I have a woman patient whose parents suffer from congenital deaf-mutism. She herself is perfectly healthy and has no disturbance of speech or hearing. She is now pregnant. What will be the outlook for her child with regard to deaf-mutism?

A.—Congenital deaf-mutism is usually due to a recessive factor. This means that an affected person must carry two abnormal genes; and so it follows that the union of two affected persons would be expected to yield deaf children only (see answer in the *Journal* of April 1, 1944, p. 481, and the amendment on April 8, p. 512). This has not happened in the present instance. Perhaps the deafness in one parent is non-hereditary, or possibly the genes concerned may be different. In view of this uncertainty no calculation of odds can be made. Whatever the true explanation may be, however, the patient can be reassured that the chances are heavily in favour of the child having normal hearing and speech.

INCOME TAX

Income from New Zealand

G. M. has investments in New Zealand, income being taxed there at the source.

* The income is liable to United Kingdom tax in spite of having already been taxed in New Zealand, but substantial relief is given from the full rate of United Kingdom tax. The inspector of taxes will require information and evidence as to precisely what tax has been paid in New Zealand. Liability attaches to income "arising" abroad, and does not depend on whether or not the income is remitted to this country. If, however, payment of tax before receipt of the income is a matter of hardship, it may be possible to arrange for the tax to stand over until the income is remitted.

LETTERS, NOTES, ETC.

Training in Electro-encephalography

Dr. F. GOLLA, F.R.C.P., Director of the Burden Neurological Institute (Stoke Lane, Stapleton, Bristol) writes: Owing to the recent development of electro-encephalography many institutions are requiring technicians trained to take charge of the apparatus. It is proposed to give to approved students at the Burden Neurological Institute a three-weeks course which will cover the field of work considered to be necessary by the Electro-encephalographic Society. Students who have made satisfactory progress will be given a certificate of proficiency.

Sterilization of Syringes

Dr. H. S. GASKELL (Stowmarket, Suffolk) writes in the course of a letter: Forty years ago the syringe was seldom used by the G.P., and I found myself adequately equipped by possessing a 1-c.cm. instrument which I boiled for an occasional hypodermic of morphine. A few years ago, however, I found that I was continually having to add to my collection of varieties and sizes. I became bored with the daily job of boiling two or three syringes, and, besides grudging the time it took, I was convinced that constant boiling did them no good. My subsequent experiments were as follows: (1) Methylated spirit. I kept them in a bowl of this, but found that it quickly evaporated, and was not persuaded that even the modicum of spirit remaining in the syringe harmonized well with either the medication injected or my patient's tissues. (2) Hard tap-water boiled and filtered to remove chalk. Separating pistons from barrels, I boiled them up about twice a week and kept them in the enamelled bowl in which they were boiled. Needles and metal rusted and became discoloured. (3) Hard tap-water with glycerin was better, but itself turned brownish after a few boilings. (4) I have since adopted the solution mentioned in the *Journal* of Nov. 20, 1943 (p. 666)—i.e., borax 1.5 g., formalin 2.5 c.cm., phenol 0.4 c.cm., aq. dest. ad 100 c.cm. Enough of this is poured into a perpendicular-sided white-enamelled photographic dish 10 in. by 8 in. by 2 in. deep to cover the largest syringe used (in my case 20 c.cm.), and this is kept covered with a similar dish. Before using a syringe I squirt out all the solution, and then draw the syringe up and down, with needle, in a bowl of boiled glycerinated water kept standing next to it, also kept covered. So far this has given perfectly satisfactory results, and the syringe markings do not disappear as they do when subjected to boiling and other methods. There is no rusting. I have abandoned the use of a 1-c.cm. syringe as I found that it barely admits 1 c.cm., and in the case of some injections—e.g., coramine—will not contain the whole ampoule, which is 1.2 c.cm. Both of the above liquids have to be periodically filtered to remove blobs of oil floating in them from oily injections. Four or five years ago I pointed out to one manufacturer that no ordinary calibre needle would suck up oil, and suggested that a large non-pointed "needle" should be supplied with each syringe with which to fill it with the oily fluid, this being replaced with one almost down to hypodermic size for injection. A year later I noticed that these came on to the market, and I always use one for oil. At home the 2-c.cm. syringe is probably the one most often used. All syringes should be of the same calibre nozzles. In my bag I carry a 10-c.cm. syringe wrapped up with needle in a piece of boric lint for use on people in their homes. It is easy to train patients to have a covered basin of boiled water ready for you on the days they expect you, in which to wash out the instrument before and after use. Some may say that this is too rough and ready, and does not "sterilize" the syringe, but I have never had a hypodermic, an intravenous, or an intramuscular injection go septic in my life. The above remarks do not apply to intravenous syringes and needles, which I always boil.

Vaccination against Smallpox

Capt. J. S. DALTON, I.M.S., writes: I hope I may be forgiven for finding the question of vaccination against smallpox still a little confusing, despite your admirable reply to Dr. Weatherhead (April 15, p. 538) on that subject. You write: "Collected data about smallpox in vaccinated persons indicate that the degree of protection is proportionate to the area of scarring." The following points do not seem to bear this out. It is difficult to believe that in primary vaccination the immunity resulting from 1/4 in. incision, with its attendant classical dermal lesion and constitutional symptoms, should be any less than that to be expected from a 1/2 sq. in. method; and, in fact, the dermal response to subsequent vaccinations in the two groups does not differ. It is now well established that in persons who have never contracted smallpox vaccination will always "take," even if in a modified form, despite any number of previously successful insertions. Furthermore, it can be shown quite easily that this phenomenon occurs irrespective of the number of incisions used in the process of inoculation. The immunity conferred by vaccination is clearly never complete, whichever method is used. I do not know of any published work on the blood immunity reactions after

vaccination for smallpox which would tend, by the results of direct experiment, to support the view you have expressed. From a clinic point of view it should be possible during an epidemic to come to a reasoned conclusion by noting the incidence and severity of the disease in groups of patients and contacts classified according to the degree of scarring. The reliability of this method, however, cannot be considered high, since it is difficult adequately to assess the relative importance of other contributory factors such as malnutrition, degree of exposure, and the degree of virulence of the organism in each case. While, therefore, it might be considered safer to use a "4-incision" vaccination method during an epidemic of variola major, I would be most interested to hear details of the scientific evidence in favour of that practice.

Red Hair and Rheumatism

Dr. J. V. C. BRAITHWAITE (Leicester) writes: In the *Journal* of July 1 (p. 33) your commentator, writing of the belief that red-haired persons are more susceptible to rheumatism than others, suggests that further investigation would be worth while. The following figures may be of interest in this connexion. Of the 9 new patients attending the Leicester Education Committee's Rheumatism Clinic in 1943, 4 had definitely red hair and 5 had a rufous tinge. Of 121 children in the Children's Hospital of the Leicester Royal Infirmary in February and March, 1944, none of whom were rheumatic, 1 had red hair and 19 had a rufous tinge. These figures are too small to be significant, but at least they suggest that a rufous tinge to the hair does not indicate a predisposition to rheumatism. Perhaps if other physicians in charge of rheumatism clinics were to communicate similar figures it would be possible to settle the question of the susceptibility of red-haired persons to this group of diseases.

Dr. F. C. EVE (Hull) writes: On page 33 of your issue of July 1 the question is asked whether—as many believe—the red-haired are specially liable to acute rheumatism. The answer given is that evidence is scanty and contradictory and that investigation is needed. For about 30 years, whenever I saw a red-haired child in our hospital beds (medical or surgical), I have asked for the diagnosis. In a striking majority the reply has been rheumatism or tubercle. In my own red-haired cases I have (later) inquired about their other infections, such as tonsillitis, coryzas, otorrhoea, sinusitis, etc. I have formed a strong clinical suspicion that red hair is a danger flag announcing that immunity against germ diseases in general is subnormal, even though the general health may be good. Hence I would suggest that investigators—instead of counting the red-heads in a large number of acute rheumatisms, as suggested—should compare the incidence of infections in a large number of red-haired children with controls of similar age groups. If the red-haired have actually a low general immunity the reason for their survival should also be illuminating, when discovered. Have they been more desirable and desirous, and thus enjoyed a compensating fertility? Ought insurance companies to ask if the hair is red?

Hirsutism in Women

Dr. CLIFFORD ALLEN (London, W.1) writes: Regarding the question in the "Any Questions?" column (July 1, p. 34) regarding hirsutism in women, might I suggest that it would probably be helpful for your correspondent to read the monograph, *The Adrenal Cortex and Intersexuality*, by Broster *et al.*, published in 1939 by Chapman and Hall. In this book I pointed out that it is by no means unusual for women suffering from adrenogenital virilism to complain of reduced sexuality, and this is restored to normal after adrenalectomy.

Why Tie the Cord?

"M.D." writes from Birmingham: Some years ago I was called by a nurse to see a baby whom I had delivered a few hours before. The nurse was a qualified midwife and had been sister-in-charge of a maternity home where many pupil midwives were trained. She had tied the cord but had delayed washing it for some time. When she came to do so she found the baby blanched and saturated with blood. I sent it into hospital with a view to transfusion, but it died. The father afterwards blamed me, and said he had been told that I ought to have "stitched the navel" and not tied the cord. I must have seen haemorrhage from the cord at some other time, for I had a habit of taking the ends of the ligature round the cord again and making another ligature, thus enclosing a part of the cord between two ligatures. Or perhaps I had noticed how many nurses seem to be incapable of making reef knots.

An Old Midwives' Tale

Dr. LEO GRUNIS (Peckham, S.E.) writes: Dr. Norman Goormaghtigh (June 10, p. 802) is under a misapprehension. The Talmudists were not quite sure about the non-viability of an eight-months babe. This was a non-Jewish teaching. So taught Hippocrates and Galen. Aristotle was of different opinion. See for more information on this subject: *Biblical Talmudic Medicine*, by Dr. Preuss. Rashi was not a physician, but a commentator of the Bible and Talmud.

LONDON SATURDAY JULY 29 1944

LOCALIZATION IN THE CEREBRUM AND CEREBELLUM

BERTRAM LOUIS ABRAHAMS LECTURE*

BY

E. D. ADRIAN, O.M., M.D., F.R.S., F.R.C.P.

Professor of Physiology, University of Cambridge

Bertram Louis Abrahams, in whose memory this lecture was given, was a medical student in the early 'nineties. He was Londoner born and bred, had a brilliant career with a University scholarship in physiology and later a registrarship at the Westminster Hospital, and ended as lecturer in physiology and assistant physician there. He was only 38 when he died, but he had an established reputation as a consultant and a scholar, and he had lived a life full of intense interests and activities—and not only in the field of medicine, for he was an ardent cricketer and Freemason and the organizer of a boys' club. But one of his chief interests was physiology, and so it fitting that his name should be associated with a lecture on a physiological theme.

The way in which we might call him to mind would be to recall and so to re-create in ourselves some of the thoughts and ideals which seem to have guided his work. Since he was a scholar of physiology as well as a clinician, he must often have had to face the perennial question of how physiology should be taught as a basis for medical work. If we dealt with this we might think of ourselves as carrying on, as it were, a discussion in which Abrahams must often have taken part 40 years ago. But I am afraid it would be found that there was little new to add to the discussion in spite of all the good advice which has been given from all sides in the past 40 years. The details of the picture have changed, but in its essentials the problem will remain as long as physiology is taught. Another theme in which Abrahams was keenly interested was that of the general physiological principles which govern the functions of the cell or the organism to injury. But here the picture has changed too much. Nowadays the physiologist has few principles left; for the emphasis has passed from the general to the particular, from the katabolism of protoplasm to the details of carbohydrate cycles. Moreover, in these uncertain times I think most of us will prefer facts to theories, however narrow the field from which they have come: so I have chosen a very limited branch of physiology, of which the most important thing we can say is that it is going ahead.

The Clinician and Cerebral Localization

The main facts of cerebral localization were established during Abrahams's lifetime and were as much the achievement of clinical medicine as of physiology. Neurology has always encouraged a very close interchange between the clinical and laboratory worker; in this country, for instance, we have clinicians like Hughlings Jackson, physiologists like Schäfer, Sherrington, and men who were both, like Ferrier and Bayliss. There are obvious reasons why both kinds of investigation are needed for the brain. It is the organ in which there is the greatest difference between man and other mammals, so the findings from animal experiments do not necessarily apply to man and must be checked and modified by observation. This lecture was delivered to the Royal College of Physicians on June 8, 1944.

Observations on patients; and men can give us far more information than animals in that we can communicate with them and find out what they feel and think. On the other hand, there are many problems involving the motor area in which results can be obtained with far greater certainty from animals than from human disease or accident.

The result of this was that until recently we knew more about the motor area in the monkey and more about the sensory and visual areas in man, though it had taken the head wounds of the last war to provide all the necessary clinical material. Since that war, however, there have been two important developments. One is the outstanding progress of neurosurgery, which has made it a much less formidable business to expose the human brain and has given us maps of the motor cortex in man to set beside those of the chimpanzee. The other development is in the use of electrical methods to investigate the brain in animals, and this has given maps of the receiving areas to compare with the clinical findings in man. I shall describe some of the information obtained by this method, for it is a relatively new physiological technique which is only at the beginning of its usefulness.

A New Physiological Technique

The technique has been made possible by the use of better electrical recording instruments and more suitable anaesthetics. The former depend on valve amplification and need not be considered in detail; the anaesthetics are the barbiturates. These have an action on the brain quite unlike that of ether or chloroform, for they reduce the persistent activity of the cortex (shown by persistent electrical waves) without preventing the arrival of the messages from the sense organs. These messages produce their own electrical accompaniment, which can be recognized without difficulty provided that it occurs against a quiet background. Thus the barbiturates allow us to record what comes into the afferent areas of the brain with a precision quite impossible with other anaesthetics which have a less selective action. In fact, their main disadvantage is that we tend to rely too much on them and to forget what they may be doing to the brain by suppressing all but the simplest activities.

What can be done with this kind of technique may be illustrated by the mapping of the visual area of the monkey's brain by Talbot and Marshall (1941). A thin pencil of light is directed to a particular spot on the retina while the striate area of the cortex is explored with electrodes leading to an amplifier and oscillograph. It is found that turning the light on and off produces electrical activity in a very small part of the striate area and that any change in the position of the illuminated spot on the retina is reflected in a corresponding change in the region of electrical activity in the brain. There is, in fact, a precise correspondence between retinal and cortical points which allows us to make a definite map of the retina as it is projected

on to the surface of the brain (Fig. 1). Points near the centre of the fovea are connected with the antero-lateral margin of the striate area, and points nearer the periphery with the posterior, mesial part. Thus, allowing for the fact that in the human brain the whole striate area has been pushed back to the mesial aspect of the hemisphere, the connexions between the retina and striate area in the monkey agree with the connexions established for man by Holmes and Lister from the gunshot wounds of the last war.

It is satisfactory to have the human findings confirmed by such a different sort of evidence, and, although the result was not at all unexpected, the important point is that the mapping can be done with a very high degree of precision, so that conclusions can be drawn as to the mechanism of visual discrimination and the like. In the anaesthetized brain, therefore, we can say that a pattern of light and shade thrown on the retina will produce a corresponding pattern of activity in the afferent fibres which enter the striate area. What would happen in the area if there were no anaesthetic is another matter. Even in the simplified conditions given by deep anaesthesia, where all but the most direct pathways are out of action, there is a good deal of editing of the messages on the way up to the brain, and if there were no anaesthetic the pattern arriving there might be much less recognizable because of interactions between neurones at the various synaptic levels on the visual pathway. And the fact that the pattern in the striate area may be recognizable to the physiologist with his electrical equipment is of little help in explaining how it is recognized by the brain in which it appears.

FIG. 1.—Representation of the retina in the visual area of the monkey's brain.

Nervous Mechanism of the Cochlea

It would have been surprising if a spatial correspondence between retina and striate area had not been found—but until recently there was less reason to expect such a thing in the auditory area, and here the electrical method has been particularly illuminating. Within the past two years the nervous mechanism of the receptor organ, the cochlea, has become far clearer, so that we have a much better notion of the sort of messages which it transmits to the brain. They have been studied by Galambos and Davis (1943) from records made from single fibres of the auditory nerve. It was found that each nerve fibre comes from receptors tuned to a particular pitch but capable of reacting to louder notes if their pitch is not far different. This agrees with the familiar Helmholtz conception, but Galambos and Davis have added the interesting point that the message which the auditory nerve fibre transmits to the brain is not itself marked by any particular frequency. It is simply a train of impulses whose frequency varies with the intensity of the stimulus; in fact, it is like all the other sensory messages which reach the brain, and could not be distinguished from them if we did not know that it came from the cochlea and so must signal sound rather than sight or touch.

Now if the pitch of the note can only be inferred from the fact that it has excited the receptors in a certain part of the basilar membrane, it follows that there must be some kind of spatial representation of the cochlea in the brain just as there is of the retina. And it has been found, first in the cat and now in the monkey, that such a representation does exist. When the cochlea is stimulated by sound, electrical activity appears in the appropriate region—the upper surface of the superior temporal gyrus—and with notes of low pitch the maximum activity (in the monkey) is in the antero-lateral, with high notes in the postero-medial, part of the receiving area

(Licklider and Kryter, 1942). Thus the apex supplies the antero-lateral, and the basal the postero-medial part (Fig. 2). Just as the movement of the hand across the visual field will produce a peak of activity to and fro across the striate area, so the up and

FIG. 2.—Representation of the basilar membrane in the auditory area of the monkey's brain.

the siren will give an activity moving to and fro of Heschl's gyrus. To have reached this position is an achievement, and it has cleared the ground for the main position—the problem of why a moving to and fro in the auditory cortex with particular intensity relations should start in us the whole time and actions appropriate to air raids. But here it is scarcely begun, and the position is defended strength.

Relation of Brain to Sense Organs

The signals which reach the brain from the sense organs arrive in the post-central gyrus (in man) at the positions we should expect; messages from receptors appearing near the vertex, those from receptors further down laterally, and so on. Again we find the cortex with peaks of activity here and there corresponding to the stimulated sense organs, and we infer what is going on in our bodies from the rise and decline of the messages. But as the electrical method has been applied to deal with animals of all sorts it has brought out differences in sensory equipment, or rather in the distance to the brain of the sense organs from the sense organs. For instance, if we compare the receiving areas of the cat and the pig we find that in the cat the fore-limb area with exact representation of the digits etc., whereas in the pig the area chiefly represented is the snout and it is difficult or impossible to detect anything about the limbs (Adrian, 1943). The reason is presumably that the cat uses its fore-limbs and claws in skilled movements

FIG. 3.—Representation of the tactile surface of the sensory area of the pig's brain.

must be precisely guided by sight and touch. The pig uses its limbs for standing and walking, and for all the skilled movements of the pig are made by the snout and the snout has an elaborate representation in the brain. A precise correlation between points on the sensory area and points in the cortical receiving area (Fig. 3), in the pig, is by the size of the cortical area in relation to the

plying it, the pig's snout is represented on a scale even more enormous than that of the human hand. Thus the snout takes place as one of the special receptive surfaces like the retina and the basilar membrane.

In other hoofed animals there is the same preponderance of afferent signals from the snout region and neglect of those from the limbs; but no one can use this method of examining the brain without realizing the importance of the sense organs in this region in every animal but man. It is implied in Sherrington's conception of the leading segments, and is shown not only in the area devoted to it in the brain but by the size of the hind nerve and the special types of receptor organ supplied by it.

The tactile vibrissa of the snout is a good example of an organ which might really be classed as a distance receptor, for one has only to look at the head of a rat to see how the snout, with the aid of its long vibrissae, comes to be literally in touch with objects more than the width of the head away. In man the sensory mechanism of the fifth nerve has lost this function of exploring space, but there are still the large number of sensory fibres to the face and its acute sensitivity to touch to remind of what is gained and lost by the erect attitude.

The Role of the Cerebellum

These are only a few of the points which have been established in regard to the cerebellum, but it is time to pass to a different field. Few neurologists of my generation can have forgotten the satisfaction induced by Gordon Holmes's analysis of the symptoms of cerebellar injury. It was almost the only map that that mysterious organ the cerebellum had any intelligible function at all. But until quite recently the clinical findings have remained more illuminating than anything from anatomical or experimental sources, and the cerebellum has kept its position as one of the most puzzling parts of the nervous system.

FIG. 4.—Receiving areas for spino-cerebellar impulses in the cerebellum of the monkey.

ous system. The newer methods have now brought distinct signs of improvement; for we have at last begun to get fairly good evidence of localization of function, or at any rate localization of nervous mechanism, in the cerebellar cortex.

A scheme of cerebellar localization was put forward some time ago by Bolk on morphological grounds. It made the anterior lobe responsible for the head, and the ansiform lobes for the arms; but since then anatomical evidence has shown that the afferent supply from the vestibular nucleus goes mainly to the posterior region and that from the spinal cord to the anterior. This in itself indicates some differentiation of function, and, by stimulating the various tracts electrically, Dow, who is largely responsible for the recent interest in the cerebellum, has verified the general distribution of the different sets of afferent fibres.

But a good deal more can be made out when we explore the cerebellar cortex with a fine needle electrode so as to pick up the impulses as they arrive in the white matter. To obtain a clear picture either the spino-cerebellar or the ponto-cerebellar acts must be put out of action, since their distribution overlaps to some extent; but when one or the other is suppressed an arrangement is revealed which is strikingly reminiscent of that in the sensory or motor area of the cerebrum.

The arrangement in the monkey is shown in Fig. 4. The marked regions show where messages arrive in the anterior lobe from the spino-cerebellar tracts when the limbs on the same side of the body are pressed or moved. The map is quite different from that of Bolk: for messages from the hind-limb go furthest forward, those from the fore-limb go to the culmen. Messages from the face appear in the lobulus simplex, not always found, and when they are they come

not from neck muscles but from the vibrissae of the face—possibly because the vibrissae have a special function in guiding the head.

The messages to the anterior lobe from the limbs are partly tactile, but most of them come from the deeper endings in muscle and tendon and in the fascia of the hand and foot. The most effective stimulus is always a pressure on the pad

FIG. 5.—Spino-cerebellar and ponto-cerebellar pathways to receiving areas in the anterior lobe and lobulus simplex.

of the foot combined with dorsiflexion of the digits—as though the limb were to take the weight of the body—but all kinds of joint movement and stretching of muscles have been effective. The localization is like that in the cerebrum, with the arrival areas arranged in the order from behind forward for hand, wrist, elbow, shoulder, hip, knee, ankle, and foot.

It is not possible to map out the distribution of the ponto-cerebellar fibres in such fine detail, but by stimulating various points on the motor cortex and picking up the discharges which are relayed to the cerebellum through the pons we can find an arrangement which is substantially the same, the hind-limb area of the motor cortex sending impulses to the most forward part of the cerebellar area, etc.

The ponto-cerebellar areas extend further out laterally than the spino-cerebellar, and there is a large region further back which does not seem to correspond to any one part of the cerebral cortex, but has a diffuse connexion with scattered points in it. For the present the relation of this relatively large ponto-cerebellar receiving area to the cerebrum must remain uncertain, and all that can be said is that there are these localized receiving areas in the anterior lobe for the different segments of the body arranged as in the diagram (Fig. 5). Probably there are other arrival and departure areas as well; indeed, in the rat (Dow and Anderson, 1942) impulses from the limbs arrive in the pyramis further back, and some of the spino-cerebellar fibres end there in the cat and monkey. But although we may be dealing with only one side of the

FIG. 6.—Comparison of the culmen (receiving area for the fore-limb) in man, the pig, and the Shetland pony.

picture it is worth illustrating it in another way—namely, by comparing the size of the culmen (i.e., the part of the anterior lobe concerned with fore-limb messages) in three different animals—man, the pony, and the pig (Fig. 6). The comparison is more than usually speculative because the evidence on which it is based is mainly derived from the cat and monkey, but the three animals are chosen because they do not differ

very greatly in size and weight but do differ in the use to which the fore-limb is put. There is evidently a great difference in the extent of the cerebellar area to which impulses concerned with the fore-limb are sent; and the comparison is also useful because it draws attention to the large fraction of the cerebellum which does not seem to be employed in any localized representation of the body and limbs. It shows, in fact, that we are still at the beginning of the story.

Conclusion

I have tried to give a sketch of a method of research on the central nervous system in which rapid advance is possible and in which it is difficult to foresee how far it may not go. But, as with all long-range research nowadays, the advance has been held up until the younger generation of physiologists can come back from the more urgent problems which they have to solve. Some day military or naval or air physiology should form the subject of a future Abrahams lecture. Compared with these problems of life and death the academic study of the nervous system seems to-day of very little consequence. All I can hope is that an account of its progress may serve as a reminder of the things which were important to us in better times, and as a reminder of a Fellow of the College of Physicians who lived when those times were taken for granted as the natural consequence of civilization.

SOME PROBLEMS IN RIBOFLAVIN AND ALLIED DEFICIENCIES*

BY

HUGH S. STANNUS, M.D., Ph.D., F.R.C.P.

(Concluded from page 105)

SIGNS AND SYMPTOMS OF HYPORIBOFLAVINOSIS

The mild constitutional symptoms, including the feeling of being "out of sorts," of loss of "pep," of mental and physical fatigue, might thus be explained, as also perhaps symptoms referred to the heart and gastro-intestinal tract.

All the dermal manifestations support my thesis, I believe. The skin has been regarded as a tissue possessing but a relatively small capillary vascularization, associated with a low metabolism, but this is fallacious. The first statement referred to the number of capillary loops per square millimetre which can be counted by Lombard's method of microscopy and left out of consideration the subpapillary plexus—the plexus which gives to the skin its colour and which itself is made up of giant capillaries. The second statement was based on the tissue-slice respiratory method of estimation, when of course the skin was not exercising any of its normally marked activities. The skin as a whole may be affected, or only those areas whose anatomico-physiological design is specialized in some direction, as I pointed out some years ago.

A mild erythema associated with fine desquamation, referred to by Sydenstricker as pityriasis sicca, may be remarked. It is most easily recognized in the skin of the forehead and face, sometimes on the hands, in the fair-skinned individual. In the pigmented skin of the native the erythema cannot be detected, but the desquamation may be noted.

In other cases the change may be obvious only where the skin is very thin, as in the antecubital fossa, or specialized, as in the case of the scrotum and in the transitional type of skin about the orifices of the body—the palpebral fissures, the nares, the free margin of the prepuce, the vulva and anus—giving rise to the lesions I have described.

Sydenstricker two or three years after his first communication on ariboflavinosis mentioned pruritus of the scrotum and vulva,

* The Lumleian Lectures (abridged) delivered before the Royal College of Physicians of London, April 18 and 20, 1944.

but made no reference to any visible lesion. On the other hand, an excellent photograph of the scrotal condition was reproduced by Spies and Cooper (1937), but with the subscription "pellagrous dermatitis of the scrotum and thighs." The lesions of the prepuce, vulva, and anus do not appear to have been recognized by American observers. Possibly they have not distinguished them from the urethritis, vaginitis, and proctitis which occur in pellagra.

The seborrhoeic lesions about the nose and in the nasolabial folds are a good example of the disturbance in an area of skin which normally possesses a rather different anatomico-physiological arrangement from the rest of the skin. Whether these lesions are of the same nature as those described by Smith, Smith, and Callaway (1941) under the designation "dyssebacia" is uncertain, as they held that the condition they described was not cured by any one of the known vitamin B₂ complex factors but did respond to autoclaved yeast or liver extract.

The affection of the vermilion portion of the lip—cheilosis—is another example of the incidence of the lesion being associated with anatomical specialization, for here the capillary loops are notably very much closer together than in other parts of the skin.

The best description of the changes in the skin capillaries is contained among observations made by Márquez Blasco and Peraíta (1940) upon patients suffering from nutritional deficiencies during the Spanish Civil War. They found that, using a dermal capillaroscope, pathological changes, least marked in simple cases of pellagra, were progressively more accentuated in proportion to the advent and advance of symptoms indicating involvement of the nervous system, including loss of visual and auditory acuity—symptoms which I shall come to shortly.

Angular Stomatitis

The angular stomatitis calls for some words of comment. The term—not a very happy one—was originally used by myself, and seems unfortunately to have persisted. It is difficult to find a better as, so far as I know, there are no words in any language which distinguish between the opening into and the cavity of, the mouth. Angular stomatitis at least serves to distinguish the lesions so named from "cheilosis," the lesion of the vermilion of the lip, though some American authors—wrongly, I believe—include both under cheilosis.

If the corners of the mouth be examined carefully, with the mouth open but produced into a pout, it will be observed that the vermilion portion of the lips does not encircle the mouth at the angles, but passes internal to the delicate fraenum which has become visible—that, in fact, the lips are prolonged on to the inner side of the cheek. This accounts for another common feature in this condition—namely, the presence on the inner side of the cheek of a linear lesion comparable to the angular stomatitis on the skin outside.

That the lesions of riboflavin deficiency become worse if nicotinic acid be given has been noted by several observers without any explanation. I suggest it is due to the pharmacological vasodilator action of nicotinic acid on an already damaged capillary endothelium.

These lesions are, I believe, characteristic, and with experience I think it may be possible to distinguish them from others produced, it has been suggested, by dentures, etc., and from the condition sometimes to be seen in those with turned-down corners to the mouth, patches of herpes, impetigo, lichen, etc. The introduction of the expression "pseudo-ariboflavinosis" by Ellenberg and Pollack (1942) is, I think, much to be deplored.

This leads me to mention the word "perlèche," a term adopted from the French which one would like to see banished from our medical literature. As pointed out a few years ago by myself (1941) in dealing with the history of this affection, it has become a habit—a bad habit, copied by one author from another, in ignorance of its original significance—when referring to angular stomatitis, to give as a synonym this foreign word. It was first used by a French doctor named Lemaître in 1886 as the title of an article—"De la perlèche: du streptococcus plicatilis." He described a condition—which closely resembles angular stomatitis—that he had observed to be common among children in the neighbourhood of Limoges,

where it had long been recognized by the inhabitants under the vulgar term "perleche"—derived from the verb *lecher*, to lick, as it had been noticed that the sufferers had the habit of "feeling for" the sore place with the tip of the tongue. Lemaistre believed the disease was due to a streptococcal infection and that it was contagious as some 10 to 30% of school-children suffered from the complaint.

Subsequent authors influenced by its supposedly streptococcal origin, used the word *perleche* to denote an impetiginous affection of the corners of the mouth. If, therefore, *perleche* were and be an impetiginous affection the word should not be used for a lesion due to hyporiboflavinosis. On the other hand, it seems to me very possible that the Limoges children were suffering from riboflavin deficiency, in which case the condition, defined as due to a streptococcus, was incorrectly described. In either case to retain the word is only to confuse the issue.

It is of interest in this connexion, however, to note that cultures prepared by Riddle, Spies, and Hudson (1940) from lesions at the angles of the mouth in cases of riboflavin deficiency yielded a pure growth of *Staph aureus* in 80% and *Str haemolyticus* in 20%, and that the organisms disappeared when the lesions healed with riboflavin therapy.

The angular stomatitis occurring in sprue appears to be due to riboflavin deficiency, some uncertainty still exists as to whether the similar condition seen in simple achlorhydric anaemia or idiopathic hypochromic anaemia and in that type presenting the Plummer-Vinson syndrome is due to the same cause. Some observers (Aykroyd Smith and Martun, Rosenbaum and Jolliffe, Machella, Spies etc.) have failed to obtain a satisfactory response to riboflavin therapy. I have met with similar cases but it must not be forgotten that a considerable increase in dosage or administration by parenteral route may be necessary before an effect is obtained.

In regard to the glossitis, Sdenstricker and his colleagues have said "The tongue is clean the papillae flattened and mushroom shaped and hypertrophic, the colour is definitely purplish red or magenta." This tongue is certainly characteristic, but whether of diagnostic value alone seems doubtful. By microscopy the filiform papillae are seen to have lost their keratinized tip, they are mushroomed out, swollen, and slightly oedematous, forming a pavement of semi-transparent hemispheres like minute jellyfish, while in the centre of each may be seen a dilated and distorted capillary loop comparable to those mentioned as occurring elsewhere. Later irregular patchy denudation may occur giving rise to a condition which has been called 'geographical tongue'.

Ocular Manifestations

The ocular manifestations of hyporiboflavinosis have received a good deal of attention of recent years. Careful studies of the effects of deficiency states on the eyes of experimental animals began with the work of Wolbach and Howe (1925) upon vitamin A deficiency in the rat and the production of corneal vascularization, a condition resembling interstitial keratitis and cataract.

In 1939 Bessey and Wolbach published their work on vascularization of the cornea in riboflavin-deficient rats. In the same year Sdenstricker and his co-workers, after the original communications by Sebrell and Butler, described the symptomatology of "ariboflavinosis" but no mention was made of ocular signs and symptoms. The following year saw the first reference to eye lesions, and a more elaborate communication appeared on the subject by Sdenstricker and his colleagues. The objective signs described included injection of the bulbar and palpebral conjunctiva and of the fornix, circumcorneal injection, engorgement of the limbic plexus, and vascularization of the cornea; further, superficial opacities and deeper interstitial changes, sometimes diffuse, sometimes patchy, were noted also congestion of the sclera and iris, and in some cases frank iritis. The authors concluded that "keratitis" is the principal ocular lesion of ariboflavinosis, the earliest and most common sign is circumcorneal injection.

The full realization of these lesions became possible only when slit-lamp microscopy was introduced for their study, a fact which probably explains their non recognition in the older

syndrome, more especially as the subjects were all coloured peoples with very dark irides.

Apart from the symptoms referable to these conditions—"itching and burning sensations," "roughness of the eyes," and photophobia—the one subjective symptom in all these cases was impaired visual acuity, referred to as dimness of vision or partial blindness associated with mydriasis.

Sdenstricker remarked "Functional disturbances of vision out of all proportion to visible changes in the cornea were present in a number of patients with oral and lingual as well as ocular lesions of ariboflavinosis" but he offered no explanation. I think American observers have failed to realize the significance of the subjective symptoms as distinguished from the objective signs. All the congestive signs I look upon as part of the general capillary dysergia, comparable to those in the skin but so situated as to be freely open to examination. On the other hand the visual disturbances I believe to be due to a lesion in the nervous system with no immediate connexion with changes in the eye. That this should be so appears never to have occurred to any of those who have published their findings, that some condition akin to a retrobulbar neuritis would best explain the symptom has never been considered apparently by American observers. I shall refer to this question later.

There are other observations recorded from the United States and elsewhere which are based, I venture to think, on misconceptions in regard to the normal. In the article to which I have already referred mention is made of a striking increase in the number of vessels composing the limbic plexus and of replacement of the normal narrow avascular zone between the limbic plexus and the sclero-corneal junction by a dense capillary network, etc. Elsewhere the statement is made "For reasons not apparent arcus senilis would seem to offer some obstacle to the extension of the capillaries beyond the sclero-corneal junction."

This is not the place perhaps, to discuss ophthalmological minutiae but inaccuracies have already crept into the literature on the subject, as in H. Jesher's *Advances in Internal Medicine* (1942) and some of our own textbooks, and are in danger of being perpetuated, so that some reference must be made to them.

My own observations—and I speak with considerable experience, having, with my colleague Prof. Brunel Hawes, examined by slit lamp microscopy the eyes of between four and five thousand individuals aged from 3 to 93 years of age, healthy and sick, with and without ocular disease—lead me to believe that there is always a complete limbic plexus and there is no narrow avascular zone between the limbic plexus and the sclero-corneal junction as has been maintained by Kruse. Scleral digitations are outlined by capillary loops. There is never any increase in the number of vessels composing the limbic plexus. Vessels certainly do cross the arcus senilis.

Few authors appear to have recognized that in the limbic plexus they are dealing with a physiologically very active capillary bed, as was so ably demonstrated ten years ago by Basil Graves in his studies on the vascularization of the cornea observations which seem to have escaped the notice of practically everyone who has written on riboflavin deficiency. It is really only a matter of the extent to which vessels are open or closed. I have found that in order to study this problem with advantage it is essential to determine the reactivity of the vessels in this area by the use of capillary dilator and constrictor drugs.

By such means—and so far as I know, no one else interested in riboflavin deficiency has used the method—it is possible to demonstrate a complete limbic plexus for example, in an old man whose limbus on first examination appears to be avascular. On the other hand, one can satisfy oneself that a completely constricted and empty capillary becomes invisible. The method also serves to demonstrate telangiectasis formation, etc.

In regard to the actual vascularization of the cornea my own experience confirms that of some others who have carried out surveys (Youmans *et al.* 1942, Wilson, 1941, Kodicek and Yudin, 1942, Pett, 1943, Tisdall *et al.* 1943, Wiehl and Kruse, 1941, Scarborough, 1942, Gregory, 1943, Sandstead, 1942, Machella and McDonald, 1943, Goldsmith, 1943, Keith Lyle

et al., 1944; Ferguson, 1944; Scott, 1944) in showing that it is not an unequivocal sign of ariboflavinosis; but that such a condition does not occur, as suggested by Vail and Ascher (1942), is incorrect. When these authors assert that—to use their own words—“Sydenstricker’s pictures as well as his descriptions suggest that what he termed corneal vascularization is nothing more than extensive engorgement of the pre-existing limbal meshwork except in cases of obvious corneal disease,” they display, I think, merely a lack of appreciation of the facts.

Another point I should like to make: my experience goes to show that it is quite impossible, owing to the great variability, to formulate any satisfactory method of notation for describing the degree of vascularity of the limbus and cornea, as has been attempted by some observers, including Keith Lyle and his colleagues (1944). No one seems to have commented on the individuality of the pattern of the intracorneal vascular network, which differs from that in vascularization associated with keratitis of inflammatory origin, etc. It is a point which may prove to have some significance.

Sydenstricker has drawn attention to the appearance of signs of ariboflavinosis in diabetes. The condition called rubeosis iridis—the subject of a communication by myself in 1942—its relationship to glaucoma, and the relationship of both to diabetes may here be mentioned.

As to the cause of the corneal vascularization, Bessey and Wolbach suggested it was of the nature of a compensatory process to bring blood into closer contact with the deeper layers of the corneal epithelium when the cornea is suffering from riboflavin deprivation. This explanation has been generally accepted in America and has found an adherent in Kruse, but to my mind it is no explanation at all and hardly consonant with Nature’s methods. It has been assumed that riboflavin exists as such in the cornea and that it reaches the cornea by diffusing from the limbic plexus. Again, it has been held that riboflavin in the cornea is destroyed by light, as it is known that the pure substance is converted into an inactive form by ultra-violet irradiation. I must confess it appears to me strange that Nature should provide the cornea with riboflavin, there to be destroyed by light.

The work of Philpot and Pirie (1943) on the eye of the ox probably points much nearer to the truth of what obtains in man. They found that all the riboflavin present in the ocular tissues is in its coenzymatic form, which is unchanged by sunlight. They give the following values in microgrammes per gramme weight: for the substantia propria of the cornea, 0.2; ocular conjunctiva and corneal epithelium, 2.0; retina, 4.0; and, be it noted, lacrimal gland, 6.5; Meibomian gland, expressed secretion, 4.0. These authors pose the very pertinent question, Is it “possible that the riboflavin of the corneal epithelium is obtained from the lacrimal secretions rather than from the blood of the limbal loops”? Personally I feel that such a possibility would best fit the facts.

It appears to have been generally assumed that vascularization of the cornea is part and parcel of the same process as limbic injection. For my part I believe that with the earliest trophic changes in the cornea, due to riboflavin deprivation owing to a deficiency in the lacrimal secretions, proliferation-promoting intercellular hormones—to use the term adopted by Loofbourow (1942) for substances released by intact cells, when submitted to damage, into the surrounding intercellular fluid—are formed which stimulate the loops of the limbic plexus to throw out new vessels.

It would also offer an explanation of the occurrence of corneal vascularization in “the vitamin-A-deficient rat which appears to be similar to, if not identical with, that associated with riboflavin deficiency. While Bessey and Wolbach referred to a change in permeability of the corneal epithelium as possibly being an important factor in causing vascularization in vitamin A deficiency, they looked to an interference with corneal respiration, and did not visualize, apparently, the possibility of that same change in permeability denying to the cornea its supply of riboflavin. The supply itself might be deficient, too, as the result of changes in the lacrimal and other glands. It is suggested, therefore, that the corneal vascularization in vitamin A deficiency may be a manifestation of a local riboflavin deprivation.

Corneal vascularization has also been described as associated with the following conditions, but further study will be necessary before their respective relationships are settled: (a) “Some unidentified component of vitamin B complex (György, Echart, and Johnson, *The Biological Action of Vitamins*). (b) Lysin and tryptophan deficiency (Trotter Day, 1942; Albanese, Randall and Holt, 1942, 1943). (c) Zinc deficiency (Follis *et al.*, 1942). (d) Sodium deficiency (Fell *et al.*, 1942). (e) Thallium deficiency (Buschke, 1913).

Neurological Symptoms

To the syndrome under discussion I admitted a group of neurological symptoms, all on the sensory side, chief among which were a sense of muscular weakness, incoordinated ataxia, and paraesthesia—unassociated with any real loss of power, any loss of sensation, or any muscular wasting—together with loss of visual and auditory acuity.

Though in the past these symptoms have been referred to by some authors as due to a peripheral neuritis, possibly influenced by ideas associated with beriberi, they have in no relation to those of that disease; nor have they anything in common with the peripheral neuritis described among alcoholic pellagrins in the United States, where the latter condition seems to have completely overshadowed all other neurological manifestations.

While I have suggested that these neurological symptoms as in the case of other parts of the syndrome, are due to hyporiboflavinosis, there is the possibility that some other factor may also be involved.

These neurological symptoms are of the same order whether associated with pellagra or not. They may be recognized in the accounts given by Scott and by Strachan of the neuritis in Jamaica, by Fitzgerald Moore in West Africa, by Land and Pallister in Malaya, etc.; but for a fuller description I am going to the case of an English child, whom I had under my care some ten years ago, suffering from an acute recurrent form of pellagra, exhibiting symptoms which we should now refer severally to nicotinic acid and riboflavin deficiencies. The child—incidentally, the first case of pellagra in this country ever known to have recovered—I was able to watch constantly day by day during a period of observation and during treatment which was with yeast and liver extract. Nicotinic acid and riboflavin were then unknown.

The symptoms were entirely on the sensory side; together they formed a complete picture of the “cerebellar syndrome”—as that term has been used in its wider sense to include muscular weakness (“cerebellar asthenia”), muscular hypotonia, ataxia, asynergia, ataxia, dysmetria, dysidiadokokinesia—together with nystagmus, vertigo, tremor, typical gait, and characteristic “pendulum” knee-jerk. At the same time there was some apparent mental apathy, hyper-emotionalism, as shown by the ease with which the child was moved to laughter or tears; and a facies somewhat reminiscent of Parkinsonism. Visual and auditory acuity were not tested. The most striking point about these symptoms was their changing measure, with rapid oscillations towards improvement or the reverse, suggestive of fluctuations in the exciting cause, a reversible disorder of function. I am going to suggest that the disorder is located in the capillary bed serving certain areas in the central nervous system and that the symptoms are the expression of a metabolic disturbance in nervous tissue produced by the capillary dysregulation resulting from hyporiboflavinosis. All those impulses serving the subconscious synergic regulation of voluntary co-ordinated movements, after relay, reach the cerebellar cortex. To them should be added those coming from Deiters’s nucleus, the relay station of the vestibular nerve.

The cerebellar cortex is the receptive centre; co-ordination presumably takes place in the very rich synapse plexus of the molecular and granular layers; while the cerebellar fibres arise not in the cortex but from the intracerebellar nuclei, the chief of which is the dentate nucleus. On the other hand, after relay in the posterior horn, the fibres subserving skin sensation, pain, and temperature pass to the ventro-lateral nucleus of the thalamus. The thalamic nuclei are the centres for the correlation of sensory somatic impulses of all kinds before transmission to the cortex, whose activities probably enter into consciousness.

The initial reversible functional disorder, which of course allowed to persist long enough leads to an irreversible lesion, situated I believe, in the synaptic structures of the cerebellum and is caused by a disturbance of its capillary blood supply. For the necessary facts I must turn to observations made on animals.

The metabolic activity of brain tissue is high in the dog. Craigie puts the oxygen consumption at 10% of the total for the whole body whereas the brain weighs only 2% of the weight of the animal.

Capillarity of Nervous Tissues

The "capillarity"—that is to say, the relative number of capillaries in nervous tissues—varies very considerably in different areas and in different nervous tissue elements. It is greatest in those areas and in those elements in which functional activity is greatest and metabolism highest. Those elements which have the greatest functional activity are the first to suffer the effects of any interference with their normal metabolic needs. As stated by Gasser (1937) the grey matter and the white matter of the central nervous system are differentiated by their metabolic needs. Greater vascularity, greater oxygen consumption and greater susceptibility are characteristic of the centres as opposed to the fibres. This is not due, however, to the cellular content of the centres. The evidence goes to show that it is bound up with the mass of fine protoplasmic strands contributed by dendrites, terminal axon arborizations, and other synaptic structures, which together go to make up what Gasser refers to as the "neurophil"—a word which I think we would spell with a 'y' instead of an 'i,' as it is presumably derived from the Greek $\phi\upsilon\lambda\acute{\eta}$ = a clan.

For its proper functioning this system of fine strands of protoplasm demands a continuous expenditure of energy. Lack of oxygen, etc., must soon bring about loss of function. In view of the fact that the surface area of a given volume of cytoplasm increases inversely as the diameter of the strands of which it is made up, it is obvious that the metabolism in the fine strands of neurophil must be much higher than that in the cell bodies and axons.

Dunning and Wolff (1937) estimated (in the cat) the relative surface of the nerve-cell bodies excluding the neurophil, in relation to the length of capillaries per cubic millimetre, in the parietal cortex, the trigeminal ganglion, and the superior cervical ganglion and showed that there was no correlation between the degree of vascularity and the cellular content of the grey matter. He inferred, therefore, that the correlation lay between the degree of vascularity and the neurophil.

The actual degree of capillarity in various parts of the nervous system has also been determined by Craigie (1919, 1938). The relative average vascularity of different regions in the central nervous system of the rat is given below in units, adapted from Craigie's figures. He showed that the number of capillaries in the grey matter is greater than in the white matter. The least vascular grey matter is still one and a half times richer than the white matter. The vascularity of sensory nuclei is greater than that of the motor nuclei.

(a) Petro lateral column (Burdach)	10
(b) Antero lateral descending tract	12
(c) Antero lateral ascending tract	14
(d) Pyramidal tract	20
(e) Postero mesial column (Goll)	24
(f) Substantia gelatinosa Rolandi	34
(g) Vth CN motor nucleus	42
(h) Xth CN nucleus	46
(i) Vth CN motor nucleus	46
(j) Ventral horn	52
(k) Vth spinal nerve nucleus	53
(l) Deiters's nucleus	54
(m) Cerebellar cortex, molecular layer	56
(n) Dorsal horn	58
(o) Inferior olive	59
(p) Superior olive	64
(q) Vth CN sensory nucleus	64
(r) Cerebellar cortex, granular layer	68
(s) Nucleus dentatus	72
(t) VIIIth CN vestibular nucleus	78
(u) VIIIth CN cochlear nucleus	84

The most highly vascularized area in this set of observations was the dorsal cochlear nucleus (84) which is twice that of the

facial motor nucleus (42) and eight times that of the fasciculus cuneatus (10). Nearly equal in vascularity to the cochlear nucleus comes the vestibular nucleus (78), followed by the dentate nucleus (72) and the granular layer of the cerebellar cortex (68). The relative position of the dorsal horn of the cord (58)—which includes Clarke's column—the molecular layer of the cerebellar cortex (56) and Deiters's nucleus (54) should also be remarked.

These figures for capillary vascularity appear to me most significant. They offer I believe, the explanation of the localization of the group of the neurological symptoms that I have described. The cerebellar syndrome is due to a disorder of function of the cerebellar "neurophil" as a result of being a tissue with high capillarity. I have not been able to find figures for the thalamus but a similar disturbance in the thalamus might account for the sensations of "burning pain" without causing loss of skin sensibility. The emotionalism might perhaps similarly be explained, while a widespread but early functional upset in the cortex might produce the Parkinson-like condition and mental dullness. The figure for layer II of the occipital cortex probably approximates to that of the cochlear nucleus, followed in descending proportion by the parietal, temporal, precentral, and insular cortex.

This distribution of functional disorders I shall again refer to when I come to consider such pathological evidence as there is, but here two points may be added.

Oxygen consumption of cats' brain, estimated by the tissue slice method, was found to be about the same in the parietal cortex as in the cervical sympathetic ganglion but seven times that of the trigeminal ganglion—confirming the view that metabolic activity lies in the neurophil rather than in the cells. This correlation is also borne out by the work of E. Gordon Holmes (1930), who showed that the distribution of cytochrome and that of cytochrome oxidase run parallel to each other and to the rate of oxygen consumption.

The sites of the primarily functional lesion causing the loss of visual acuity and that causing loss of auditory acuity are uncertain, but I believe the lesions in the two conditions are of the same nature as elsewhere in the nervous system—i.e. a capillary dysergia. The high figure given for the capillarity of the cochlear nucleus is worthy of note but there is none for the lateral geniculate body. Sydenstricker, who found the fundi normal, seems to suggest that the dimness of vision in his cases was due to the changes in the cornea, loss of auditory acuity he does not mention. It will be remembered, however, that Fitzgerald Moore also found a normal fundus in his early cases but afterwards he ascribed the amblyopia to a retrobulbar neuritis as I had done, and of course later changes in the disk become obvious.

In the Spanish Civil War Grande Covan and Jimenez Garcia (1940) noted, among the syndromes they described, one which consisted of loss of visual and auditory acuity, commonly associated with the affection of the tongue and lips and neurological symptoms including paraesthesiae and ataxia.

Impaired hearing was of course recorded by the older pellagrologists, as also were the ophthalmological conditions (Quaglino, Ferradas, Guaita, Dentu Rampoldi, Ottolenghi). During the present century really very few observations have been published (Whalley, 1909, Tucker, 1911, Ridlon, 1916, Calhoun, 1918, Jaensch, 1930, Krivlov, 1932, Cronin, 1933, Levine, 1934, Carrol, 1936, Fine and Lachman, 1937, Laval, 1939, Mendoza Gonzales, 1941, Alessandri *et al.* 1942).

I think the evidence, so far as it goes, supports the idea that the condition in pellagra is essentially the same as that met with apart from pellagra and included in the hyporiboflavinosis syndrome. I should prefer to call it a (retrobulbar) optic neuropathy.

The lack of systematization of the lesions in the central nervous system has generally been remarked (Kinnier Wilson, 1914, Greenfield and Holmes, 1939, Pauls and Deprecq, 1939) and remained unexplained up to date. There is a systematization but it is one based on the neurophil.

Pathology

The post-mortem findings in riboflavin deficiency in animals are not very conclusive in regard to the nervous system, but

on the whole would seem to lend support to the views expressed above (Street and Cowgill, 1939; Zimmerman, Cowgill, and Fox, 1937; Page, 1937; Wintrobe, Mitchell, and Kolb, 1938; Phillips and Engel, 1939).

There is no certainty concerning the pathological changes in the viscera in man in nicotinic acid and riboflavin deficiencies. It is just worth remembering, however, that degenerative changes occur in the heart muscle in pellagra, that the liver always shows fatty changes, most marked perhaps in infantile pellagra, while in the dog "yellow liver" is characteristic of ariboflavinosis. Scott mentions myocardial changes "with dilatation and congestion of the cardiac capillaries," and an angioma-like condition in the heart.

There is, so far as I know, no account of the post-mortem findings in human riboflavin deficiency. No case of "ariboflavinosis" has come to necropsy in America. None of the cases described by Fitzgerald Moore and by Landon and Pallister found its way to the pathologist. I have therefore turned to the detailed pathological records by Scott upon two cases of the Jamaican disease which he called "central neuritis" but which I have ventured to suggest, in the light of present-day knowledge, may have been acute hyporiboflavinosis. I wondered whether one would find a pathological picture in the central nervous system with irreversible tissue changes, such as might be expected to follow the early reversible functional disorder that I have supposed to occur. It is not possible to deal with these here in detail, but I believe Scott's findings support my thesis.

Scott noted the many points of resemblance between his own findings and those of Singer and Pollock (1913) in pellagra, who in turn had stated that the histopathological picture in pellagra was identical with that described by Adolf Meyer (1901) as "central neuritis." This condition, later referred to by Pearson (1920), I have little hesitation in suggesting is the later stage of the functional disorder I have described. It starts, I believe, in the neurophyl as the result of the capillary dysergia, and spreads to the cell, to be followed by changes in the axone.

The changes found in the pseudo-encephalitis of Wernicke associated with vitamin B₁ deficiency, consisting of capillary dilatation in certain areas of the nervous system—viz., the paraventricular grey matter of the third ventricle, the mammillary bodies, the peri-aqueductal region, the corpora quadrigemina, and the floor of the fourth ventricle—make an interesting comparison.

If, as I have suggested, riboflavin deficiency interferes with the normal functioning of the capillary, with the production of a tissue anoxia, it would seem of interest to compare the nervous symptoms so produced with those referable to the nervous system in chronic carbon monoxide poisoning.

C. K. Drinker in his monograph upon the subject states that headache occurs in 74%, dizziness in 50%, burning of the eyes in 32%, gastro-intestinal disturbances in 24%, drowsiness in 28%, cardiac disturbances in 18%, insomnia in 20%, faintness in 12%, neurological and mental symptoms in 17%. Among the last-named are giddiness, nervousness, emotionalism, tremors, muscular weakness, increased reflexes, neuromuscular pain, sensations of numbness and chilliness, paraesthesiae, ataxia, muscular incoordination, disorders of vision and hearing, neurotic and psychotic manifestations.

The general resemblance of these symptoms to those I have described in the syndrome here dealt with is, I think, worthy of note, especially when it is remembered that carbon monoxide and cyanide are believed to operate by inactivating cytochrome oxidase and thereby inhibiting oxygen consumption by preventing electron transfer—cyanide by uniting with the iron when in the "ferric" form, carbon monoxide when in the ferrous form. Of cyanide I shall not speak, but I might mention here that Quastel (1943) has recently analysed the evidence concerning the inhibition of oxygen uptake by narcotics, and concludes that flavoprotein is the sensitive factor.

Summary

An attempt has been made to disengage from the clinical affection we call pellagra a group of symptoms which may also be met with

as a more or less complete syndrome apart from those symptoms generally recognized as due to a nicotinic acid deficiency.

This syndrome includes a good deal more than that to which American authors have given the name "ariboflavinosis." At differences are; however, I think, a question of the comparative intensity and duration of the underlying pathogenic process.

I have considered the whole syndrome, for the sake of convenience, as due to riboflavin deficiency—a hypo-riboflavinosis should prefer to call it rather than an a-riboflavinosis—but some uncertainty must still exist as to whether any other factor in the complex plays a part.

All the symptoms of the syndrome respond to treatment with yeast. It is suggested, in the absence of any knowledge on the subject, that we are warranted in making the assumption that the cells forming the capillary endothelium require all those elements needed by other cells in the body for their normal metabolism—sugar, oxygen, etc., including riboflavin.

It is further suggested that the first tissue to suffer the effects of riboflavin deficiency is the endothelium of the capillary system; the initial result is a reversible functional disturbance of the capillaries—a "capillary dysergia"—which at the present time cannot be more accurately defined, but which is manifested by dilatation of these vessels and impaired flow; that in turn there is an interference with the normal cellular metabolism and in consequence a derangement of tissue function by disturbance in the *milieu intérieur*; and that the derangement of tissue function is relatively greatest in those tissues which possess the highest degree of capillarity and whose metabolism is greatest.

So long as the intensity of the functional disorder be not too great and so long as it do not persist too much, complete recovery may take place, otherwise irreversible processes occur which lead to pathological changes.

The hypothesis put forward would appear to offer an explanation of the incidence of symptoms and distribution of signs in riboflavin deficiency.

The interference with tissue-cell metabolism is probably of the nature of an anoxia in its wide sense.

It is suggested that disorders of capillary function—"dysergia"—quite apart from affections of the rest of the vascular system, may play a much more important part than has commonly been supposed in the pathogenesis of many conditions, including pellagra due to nicotinic acid deficiency.

At the risk of appearing mono-ideistic, I cannot help feeling there is perhaps a wide field awaiting investigation along such lines—a field embracing such widely separated conditions as fibrositis, rheumatism, some psychoses, and neuropathies.

POST-OPERATIONAL STRAIN IN THE NAVY

BY

DESMOND CURRAN, M.B., F.R.C.P., D.P.M.

Temp. Surg. Capt., R.N.V.R.; Consultant in Psychological Medicine to the Royal Navy; Psychiatrist to St. George's Hospital, London

AND

GERALD GARMAN, M.B., D.P.M.

Temp. Surg. Lieut., R.N.V.R.; Neuropsychiatric Specialist

The concept of an operational strain syndrome is open to criticism on a variety of grounds. There is, for example, little evidence that psychiatric breakdowns associated with operational stress differ symptomatically from those that are not. Moreover, not all reactions supposedly associated with operational stress are due to it, and in wartime there is a very real danger of over-emphasizing the dramatic, such as exposure to enemy action, when less dramatic events, such as the regimentation and frustration of Service life, separation from home, and domestic difficulties, may really possess more significance. Again, the conception of an operational strain syndrome runs the grave risk of creating an honourable as opposed to a dishonourable or at least less honourable category.

There is, however, yet another objection, to which curiously little attention seems to have been paid—namely, that the concept is descriptively misleading in that most men break down after, rather than during, a period of stress; and it is with the phenomenon of post-operational strain that this paper is mainly concerned.

Discrepancy in Sickness Rate Afloat and Ashore

There are a number of observations which are not agreeable to the view that psychiatric casualties attributable to operational stress occur during operational stress. Thus, starting with the psychiatric problems as seen afloat, naval medical officers serving in ships have not hesitated to point out to naval psychiatrists serving ashore that, although at sea evidence of fear may exist in plenty, psychiatric cases do not. On the other hand, naval medical officers serving in naval establishments ashore, such as drafting depots, are keenly aware of the size and importance of the psychiatric problem in naval medicine, and this opinion is fortified by service in a naval hospital. That there is in fact a striking difference in the incidence of psychiatric disorders ashore and afloat is amply confirmed by calculations kindly made by Surg. Cmdr. J. A. Fraser Roberts, R.N.V.R., Consultant in Medical Statistics to the Navy, although for Service reasons it is not possible to publish the relevant figures at the present time. They can be up to ten times as numerous.

This discrepancy cannot be accounted for by the accumulation and concentration of the neurotic in naval depots ashore (e.g., in one naval depot 90% of psychiatric out-patients are passed fit for service at sea). Nor is the answer to be found in the ingenuously cynical view that men reporting sick ashore with psychiatric symptoms necessarily do so with any conscious or unconscious intention to evade their draft or their duty. Again, to see many of these men should convince anybody that they are not faking their symptoms.

Development of Post-operational Strain

It is submitted that *reduction* of "tempo" on coming ashore from sea is a potent factor not sufficiently recognized as a cause of symptom development. Men seem to develop a need for the stimulation to which they are accustomed, even if it is unpleasant. Alteration or reduction in the accustomed stimulation is a frequent cause of men reporting sick. It seems reasonable to regard the process as analogous, in slow motion, to the normal experience of feeling worse after danger than during it: the reaction after any excitement is often more disturbing than the excitement itself, especially if opportunities for a satisfactory outlet or distraction are lacking.

The state of physiological anxiety or tension is a condition of heightened responsiveness and preparedness, associated with well-known somatic accompaniments. At sea this increased responsiveness and readiness is not merely acquired passively by "conditioning," but is actively taught and fostered, both individually and collectively; for the safety of the group may depend on the degree of its development. Far from being pathological, it acquires the quality of a virtue which all should share, and is both necessary and completely appropriate. Some permanent degree of tension is thus established and maintained at sea as a biological necessity in order to cope with the emergencies that may at any moment arise; but after an initial relatively short-lived period of adaptation it obtrudes into consciousness only as the result of a special increase or decrement. A partial analogy may be drawn to the initial awareness of the noise of the dynamos on going on board, which then fail to be noticed until their cessation may once more call attention to their previous presence.

When a man goes ashore the increased tension that he has acquired at sea does not disappear immediately; the time required for it to do so varies considerably and is seldom less than a few weeks, although in some it may continue for months and even occasionally for years. During this individually variable period the increase of tension, which at sea was appropriate and necessary, is now incongruous. If a man starts violently at a sudden or loud noise he becomes aware of this incongruity, for sudden noises possess a much less ominous significance than they did. Further, he is aware of the discrepancy between his behaviour and that of his mess-mates, and he may become the object of their gibes. From the subjective standpoint, the increased tension that he has acquired is unpleasant and uncomfortable because it is inappropriate to the reduced tempo of his life; and objectively he shows the clinical signs of an anxiety state. The extent to which he will interpret his condition as evidence

of an illness will depend upon his intelligence and personality and many other factors, and strong reinforcements may exist or develop to regard it as an illness, owing to unrecognized motives of an unworthy kind.

To recapitulate. Men at sea develop a condition of tension, resulting in increased responsiveness and readiness that are physiological and appropriate; but on coming ashore this tension state may become pathological, because it is inappropriate or unnecessarily intense having regard to the altered and reduced tempo of the life. The greater the lag that is shown in adjusting to the tempo that is suitable to the new environment, the more does the state that was previously within normal limits and physiological stand out as being abnormal and pathological. The basic reaction should be regarded as a psycho-biological occurrence, with a good deal of emphasis on the biological component, although more purely psychological determinants (of an impure or even unworthy kind, perhaps) may, and often do, come in secondarily.

Confirmation is readily forthcoming that the sequence of events described above is the correct one for many cases. Thus, when seeking for evidence of an objective kind about a patient's previous condition, it is not uncommon to hear surprise expressed by a shipmate that he should have fallen sick. There may be excellent testimony that the man was apparently normal and aroused no suspicion of disability on board, and equally good testimony of inefficiency and altered behaviour ashore. Again, men with first-class personalities not infrequently develop the symptoms of a severe anxiety state after admission to hospital for treatment for some incidental physical ailment. A careful history will also often disclose that the onset of anxiety symptoms coincided with in-from-sea leave. In this connexion it is noteworthy that the story of onset dating from a previous experience of enemy action is frequently quite inconsistent with the facts and is a retrospective falsification.

It may also be observed that certain men of a good type with persistent anxiety symptoms will ask to return to sea despite clinical signs that might appear prohibitive, and this endeavour to make the environment fit the state and to banish the sense of incongruity is often successful. The uneasiness of some combatant officers away from the front line and the desire of certain fighter pilots to spend their leave either spotting in the Channel or at sea in a destroyer appear to be of somewhat similar origin, and it detracts nothing from the courage of these gallant men to interpret their behaviour as being the expression of a biological need to sustain tension. The difficulties and breakdowns that occur in civilian life on retirement are perhaps examples of the same principle. Finally, the modicum of success which followed "conditioning" by providing psychiatric patients with some of the experiences of war (e.g., artificially produced sounds of dive bombers) may have been due to the manufacture of an artificial environment that was appropriate to the tension which these men experienced. It was soon recognized, however, that a return to duty was equally effective and more economical of manpower.

It seems plausible to postulate that reactive depression is often reactive to reactive anxiety. Reactive depressions pre-eminently occur in men of good personality after long periods of stress, and the affect is appropriate to a sense of having failed to run the course and of having succumbed to an illness bearing a stigma of shame. A belief of having been found wanting in "will power," a sense of impaired efficiency, lack of confidence, and a fear not so much of further enemy action as of experiencing again the tension that it produced, all contribute to the production of these states. The implicit teaching that underlies morale is such that few men fail to experience some sense of insult and guilt when pathological anxiety is experienced, and this may be why a measure of depression is so often mingled with anxiety states. This sense of guilt is less common in civilian life, and depressive accompaniments of anxiety states are also less frequent.

Prediction and Selection

The fact that those who finally succumb to stress form only a small minority would seem to constitute a weighty argu-

In very young infants, however, owing to certain physiological peculiarities in their skin, positive Schick reactions in susceptible individuals are much less readily evoked, and estimates of immunity obtained by the use of this test during the first few months of life are thus often fallacious. Consequently, the Schick reaction of the recently confined mother, which for practical purposes may be accepted as reflecting the antitoxin titres of both her own and her infant's blood, thus acquires a particular significance in the epidemiology of diphtheria in early infancy.

The following study was made during 1942 and 1943 in a maternity department of a hospital on the south-eastern outskirts of London. A large proportion of the 250 recently confined women examined came from districts in which housing conditions are good. Many of them, however, had spent the earlier part of their life as school-children in one of the Metropolitan boroughs of London, and, since it seemed possible that this might have had some effect upon their immunity as a group, the findings for these women have been recorded separately. The average age of the 250 women was 28.5 years. The Schick tests were carried out according to the usual technique 0 to 5 days after delivery. The sites of inoculation were examined daily for 7 days. The results of the tests are shown in Table I.

TABLE I.—Schick Reactions (Totals and Percentages)

Groups of Women Examined	—ve	0—ve	—ve	0—ve	Totals
London-bred	54 (45.7)	10 (8.5)	43 (36.4)	11 (9.4)	118
Others	75 (56.8)	5 (3.8)	45 (34.1)	7 (5.3)	132
Totals	129 (51.6)	15 (6.0)	88 (35.2)	18 (7.2)	250

Schick Reactions in Non-parturient Women

Since it seemed possible, from these rather high rates for positive reactions among recently confined women, that such persons might be more sensitive to diphtheria toxin in the puerperium than at other times, a further series of tests were made upon a group of 62 women who had been admitted to the same hospital for medical or surgical treatment. Their social surroundings were the same, and their average age—31.1 years—was nearly the same. Of this group 58% proved to be either positive or pseudo-positive reactors, so that there seems to be no reason to believe that the puerperal state gives rise to any heightened susceptibility to this toxin. The London-born women in this group also showed a rather lower proportion of positive and pseudo-positive reactors (52.6%) than the remainder.

Positive Reactors in Recently Confined Women in Various Age Groups

In the group of 250 recently confined women there were statistically significant differences between the proportions of positive reactors in the following three subgroups: those 24 years and under; those between 25 and 34 years; and those 35 years and over. The numbers falling into these subgroups, the numbers showing positive or pseudo-positive reactions, and their respective percentages are set out in Table II.

TABLE II

Age Group	No. Tested	No. Positive	% Positive
14 years and under	88	60	68
15 to 34 years	116	67	58
35 years and over	46	17	37

Eighteen of these 250 recently confined women and 22 of the whole group of 312 stated that they had suffered from clinical diphtheria: 14 of them were among the 137 London-born women—a proportion which might be expected from the ratio of notified cases to child population in the Metropolitan boroughs between 10 and 20 years ago (see Wright and Wright, 1942). Of these 22 women 12 reacted negatively to the Schick test, 7 positively, and 3 pseudo-positively. Only 4 of the 312 women had been immunized prophylactically against diphtheria; 4 of them had a negative and one had a pseudo-positive reaction.

Changes in Schick Reactions at Short Intervals after Injection of Toxoid

It appeared unlikely that so large a proportion of women living in a semi-urban environment could have escaped immunization through casual contact with diphtheria cases or carriers at some period of their lives. It seemed much more probable that most of them had undergone some degree of immunization in the past, but that the exposure was too slight or at too remote a date to maintain their circulating antitoxin titre at or above the critical level for the Schick test. To examine this possibility some of the positive reactors were injected intramuscularly with 1 c.cm. of T.A.F. on the third or fourth day after their Schick test. A second Schick test, in which toxin alone was used, was carried out four or six days after this immunization. The diameters of the hyperaemic areas present at the peak of the responses were measured, and in most instances the relative intensities of the first and second reactions were noted roughly for comparison. With the help of this combination—the comparatively large "recall dose" of toxoid and the two Schick tests—it was hoped to distinguish those women in the two subgroups: (a) "fully susceptible" and "sub-immune," from (b) "positive immune" and "potentially immune" (see Glenny, 1925).

Of the two subgroups of 20 women each whose tests were repeated 4 and 6 days after receiving the "recall dose" of toxoid, 10 and 9 respectively showed second reactions two-thirds or less the size of those originally found. In the 6-day group, possibly owing to the rather longer interval, the intensity of the hyperaemia in the second test was in almost all instances notably less than in the first. Such changes in the size and intensity of the reaction almost certainly indicate that the second injection of toxin had been more fully neutralized than the first, and consequently that an appreciable amount of antitoxin had been formed actively by such women—a response to this antigenic stimulus that would be unlikely to take place so promptly except in the tissues of an already partially immunized person.

From these observations it seems likely that at least half, and perhaps more, of the positive reactors among the recently confined women fell into the categories termed by Glenny the "positive immune" and the "potentially immune." At some time in the past they would probably have reacted negatively to this test, but, possibly owing to long residence in less densely populated districts, they have relapsed into the positive state.

Schick Reactions in the Infants

Schick tests were also carried out at some time during the first 5 days of life upon the infants of 145 of this group of women. The injections were made either in the scapular region or on the outer aspect of the forearm near the elbow. All the test sites were examined daily for 7 days, except in a few

Totals		122		23	
Percentages		84.1		15.9	

instances in which the mother or infant had left the hospital on the fifth or sixth day. In the infants no reaction was regarded as positive unless it was seen to be present on at least two such examinations. The findings in the present series, together with those of certain earlier workers, are shown in Table III.

In 122 of the 145 mothers and infants tested their reactions agreed. In the remaining 23 there was disagreement—the mother being negative and the infant positive in 2 instances, and the reverse in 21 instances. The circumstances under which these disagreements occurred were as follows:

Mother Negative and Infant Positive (2 instances).—In the first of these the mother was pseudo-negative and the infant reacted only faintly on the second and third days. In the other the woman was definitely negative and the infant definitely positive. It may be observed that instances are recorded in which a relatively high antitoxin titre in the maternal blood is accompanied by a much lower, or even untitratable low, level in the cord blood. Von Groër and Kassowitz (1915) found three such instances in their series.

Mother Positive and Infant Negative (21 instances).—In 6 of these instances the mothers were definitely positive. Three of their infants showed a positive reaction on one day only, and were accordingly classified as negative; in one other instance the mother had had diphtheria 24 years before. In 5 other instances the mother was classified as a faint reactor, and in none did the infant show any sign of a positive reaction for even so short a period as 24 hours. In the remaining 10 instances the mothers, three of whom had had diphtheria in childhood, showed pseudo-positive reactions. One infant in this group showed a positive reaction on one day only.

The most common form of disagreement was thus a failure of the infant to react positively when the mother was positive, and especially when she was either a faint or a pseudo-positive reactor. This state of anergy was present in about one-quarter of the infants in whom a positive reaction might have been expected from the result of the test upon the mother. The proportion is rather smaller than that found in the earlier studies, and is probably due to the frequent examination of the test sites in the present series. Moreover, the lighting conditions for examining the present group of infants were unusually favourable.

Discussion

The belief is still widely held that the great majority of young infants possess a high degree of congenitally acquired passive immunity to diphtheria for some months after birth. Two circumstances in particular have contributed to this belief. First, many of the observations upon specific immunity in newly born infants were made in Vienna and other European cities, in whose populations diphtheria was particularly prevalent, and the results of these early surveys have been applied rather freely to other places and times without allowing adequately for local differences in the endemicity of the disease. Secondly, insufficient attention has been paid to the phenomenon of skin anergy which is shown by young infants to diphtheria toxin and other noxious agents capable of producing delayed erythematous reactions, so that, for this age group, many negative Schick reactions have been interpreted erroneously in consequence. Together, these misconceptions have led to an exaggerated estimate of the prevalence of congenital immunity during the first few months of life, and the reliance which has been placed upon this supposed insusceptibility is unfounded in a large proportion of instances.

The present observations indicate that considerably less than half of the infants born to women living in a typical outer London suburb have any adequate congenitally acquired immunity to diphtheria. So infrequently do the mothers come into contact with toxigenic *C. diphtheriae* that their circulating antitoxin concentrations fall to levels considerably below the critical titre for the Schick test. While a large proportion of the positive reactors among these recently confined women are themselves immune in consequence of the promptitude with which their antitoxin-forming tissues respond to the secondary stimulus of the specific toxin, their low antitoxin titre during pregnancy confers little or no immunity upon their infants.

At the present time the trend of mortality of infants under 1 year from diphtheria in England and Wales is a declining one, and so long as this fall continues no additional prophylactic precautions seem to be required. In the event of an epidemic rise, however, either in some particular locality or in the country as a whole, two possible measures might be instituted. First, infants might be immunized considerably younger than is now the custom: this procedure has the disadvantage that very young infants seem to respond less well to prophylactic immunization than older infants or young children. Secondly, as Dudley (1934) suggested, it might be desirable to immunize all Schick-positive pregnant women during the latter part of the

gestation period. Such a procedure would at the same time immunize any woman who was susceptible and raise the maternal antitoxin titre to a high level about the time of the birth of the infant.

RADIOTHERAPY OF ECTOPIC CALCIFICATION

BY

E. MILLINGTON, D.M.R.

Radiotherapist to the Royal West Sussex Hospital, Chichester

For some years radiotherapists have been treating with success deposits of calcium in the tissues, but unfortunately few outside the specialty seem to know of them. In two recent books on bone and joint conditions (McMurray, 1937; Watson-Jones, 1943) no mention is made of radiotherapy at all in this connexion, and few writers on general surgery have commented on this mode of approach, although in America the use of x rays in treatment is much more widely appreciated, and standard works, such as that by Comroe (1941), give full credit to radiotherapy. Ectopic calcium deposits may appear almost anywhere in the body, but of most interest here are those occurring in muscles, tendons, and bursae, as such deposits are in many cases painful and thus attract attention and demand treatment. The shoulder region is often affected, as in the calcified subacromial bursa or supraspinatus insertion, and the olecranon and Achilles bursae are also quite often involved in this process.

No convincing explanation of this deposition has as yet been given, and the formation of actual bone is even more obscure. Many theories have been put forward on the subject; these are summarized by McCurich and Millington (1943). It is only with calcification, and not with true ossification, that we are now concerned, as x-ray treatment has no effect on formed bone, but only on calcium deposits. Calcium is frequently deposited in dead or devitalized tissue, possibly because of the change in pH in such regions, and the lesion with which we are dealing are mostly traumatic in origin, with pain dating from some injury or strain and becoming more persistent with time and the usual methods of treatment. X-ray examination eventually shows the presence of shadows due to the deposition of calcium of an amorphous and flocculent nature. It seems questionable whether it is the calcium that causes the pain, but in most cases if the calcium can be removed the pain also goes to a large extent, and perseverance with physiotherapy will then complete the cure.

Many surgeons recommend and practice surgical removal of the calcium. It was sometimes found at operation, however, that what appeared radiographically to be a large mass of chalk could not be distinguished from surrounding tissues when exposed, and at other times only a small amount of chalky fluid was seen; so there is no guarantee of cure from operation. X-ray treatment offers a method which is devoid of trauma and risk, and in any case does not preclude any more drastic methods later should it fail. The mode of action of the rays is not known, any more than it is with other applications; it may be due to alteration of blood supply, or possibly to some change in the pH of the irradiated part. The dosage is small and not harmful, there are no known ill effects, and the patient is not laid up or incapacitated in any way; it must be realized that the effects of x rays are not usually manifest for some time after the treatment has been given, as a rule it is some four to six weeks before there is any change in the radiographic appearances even if the pain has been relieved earlier.

Technique

The technique of treatment is not standardized, and good results are obtained by widely varying methods, but one technique which has proved satisfactory in the hands of quite a number of therapists employs repeated small doses of highly filtered x rays—namely, 200 r at 200 kV with 0.5 mm Cu and 1 mm Al filter, given once a week for four doses. Re-examination of the part after four weeks will often show absorption of most of the calcium, if not, the course may be repeated. Only a small area is treated, and there should not be any skin reaction or adverse systemic effect.

Three typical cases are reported below—one occurred in the subacromial bursa, one in the tendo Achillis bursa and one in the soft tissues of the hand. All were of long standing and with treatment all cleared up completely, both radiologically and clinically, although the cause was quite different in each case.

Illustrative Cases

Case 1—An area of calcification was found under the deltoid on x-ray examination of this patient, who had had pain and stiffness in the shoulder for five years after falling from a horse. The pain had become continuous and had been accentuated by a course of radiant heat administered by the patient to himself. A single course of treatment was given as above with relief of pain two days after the first dose and no return to date (nine months). Radiographs taken four weeks after treatment showed no definite opacity, only some scattered mottling was seen.

Case 2—A bursitis of the tendo Achillis region followed injury to the heel 12 months ago in this patient suspected of gonococcal infection. Radiographs showed a definite patch of calcification, and a small sinus formed which discharged a creamy fluid at intervals. After one course of treatment the pain was much easier, but the discharge continued and radiographs at this stage revealed considerable diminution in size of the patch of calcium but not complete regression. A second course was therefore given after which the discharge stopped, pain vanished, and radiographic examination showed complete disappearance of the deposit.

Case 3—Localized deposits of calcium were found in the hand of this patient who is suffering from a very low grade type of Hodgekin's disease. The deposits were palpable and very painful, with some oedema of the surrounding tissues. An attempt was made at surgical removal, but this was unsuccessful as no discrete deposit was found on exposure of the region involved. After one course the pain had gone and radiographs showed almost complete disappearance of the calcium, so no more treatment was given. The patient is well to date, after one year, but has grown other deposits elsewhere which have not yet been treated.

Comment

In these three examples ossification had not occurred, and it must be emphasized that radiotherapy is efficacious only when unorganized calcium is present, but nevertheless in early ossifying lesions x-ray treatment will often prevent the formation of bone from the preliminary calcium deposits. In the elbow region a deposition of calcium occurs before ossification in the antecubital muscles and in the early stages will disappear if treated with radiation, some American surgeons even recommend the prophylactic irradiation of elbow injuries to prevent subsequent myositis ossificans. Haematoma may be treated in the same way with small doses of x rays and ossification be prevented in most cases. Unfortunately organized deposits of calcium in the form of biliary and urinary calculi show no response to doses of x rays.

A post-war programme of measures to reduce road accidents has been published by the Pedestrians' Association (180, Fleet Street, E.C.4). The proposals include better speed control, stricter enforcement of the law, a higher standard of efficiency among drivers, and a safer motor car. The Association takes the view that the 30 m.p.h. in built up areas is too high a limit for safety and that the limit should be 25 m.p.h. with higher speed limits on main roads outside the built up areas. Proposals for a safer car include placing the engine at the rear, giving the driver a better view of the road, greater manoeuvrability, a shock absorbent frame, and flexible upright fenders in front of the leading wheels with a net catcher between them.

Medical Memoranda

General Hypersensitivity to Sulphanilamide after Surface Application

Although the occasional development of general hypersensitivity to sulphathiazole after the application of that drug to skin lesions has been described (*J Amer med Ass* 1943; 121, 406), no mention is made in the Medical Research Council's War Memorandum No 10 (The Medical Use of Sulphonamides) of a similar occurrence with sulphanilamide. The following case may therefore be of interest.

A telegraphist aged 21 complained on March 8, 1944 of a sore throat of 24 hours' duration. His temperature was 101.6°, pulse 100, and respirations 20. The tonsillar lymph glands were palpable and tender, both tonsils were slightly swollen, and the fauces and oropharynx were injected. He was given 2 g of sulphanilamide at 8 p.m., to be followed by 1 g 4 hourly. Next morning his temperature had fallen to 97.4° and his throat felt much better. At 8 p.m., however, 24 hours after sulphanilamide therapy had been started, his total intake being 8 g, the temperature was 103° and a generalized skin rash had developed. It was most marked on the dorsal surfaces of the hands on the forearms and on the feet and legs, and it was morbilliform in character except on the hands, where there were some clear vesicles about the size of a pin-head. The throat was only a little sore and injected. No more sulphanilamide was given and the temperature fell abruptly. It was below normal on the 10th but was raised, up to 102° on the following 4 days. The rash faded slowly, and on March 13 it was rather more urticarial than morbilliform. Its distribution had also changed, for it was almost as intense on the front of the chest as on the hands and feet. Ten days later the only abnormality was slight scaling of the skin of the hands, forearms, ankles, and legs, which persisted for a further 3 weeks.

It was found from his previous records that sulphanilamide paste had been applied to an incised wound about 2 in. long on the front of the right leg from Oct 9 to 12, 1943—i.e., for four days—five months before this illness. The only other occasion on which he had received medical attention since he was a child was in 1940, when he had a cough for which he was given a 'black bottle'. Thus there seems to be little doubt that the appearance of pyrexia and a rash after only 24 hours' treatment was due to sensitization by the surface application of the drug.

Weil's Disease without Jaundice

The name Weil's disease has been criticized on the ground that Weil was not the first person to describe the disease, but alternatives such as spirochaetosis icterohaemorrhagica and spirochaetal jaundice which lay so much stress on the jaundice, probably result in many cases being misdiagnosed. We have recently had four consecutive cases in which there was no jaundice.

FOUR RECENT CASES

Case 1—A child aged 4 fell into a brook which was flooded with storm water. The accident occurred in the winter and was followed immediately by a brief febrile illness which was diagnosed as pulmonary collapse and treated with sulphathiazole. Chest symptoms and signs soon disappeared but the child remained unwell and refused to eat. On the eleventh day she vomited and there was an abrupt rise in the temperature to 105°. On admission to hospital two days later her temperature was 103°, her conjunctivae were injected and there was a trace of albumin in the urine. The serum agglutinated *Leptospira icterohaemorrhagiae*. The acute symptoms rapidly subsided, no other physical signs appeared and the urine was normal after the first day. Nevertheless it was some months before the child was really well again and on several occasions there was a slight rise in the evening temperature.

Case 2—This case was discovered accidentally after a short febrile illness originally diagnosed as influenza. The patient was a young doctor who worked in one of the Emergency Public Health Service laboratories. He described an abrupt onset of malaise with fever, pains in the limbs, headache and sore eyes. After six days he had apparently recovered but realized he still lacked energy. He therefore continued to take his temperature and a fortnight after the onset of his illness he found it was 100° on two consecutive evenings. The head of his department, who knew there was no epidemic of influenza at the time, insisted on routine agglutination tests on his serum and the diagnosis of Weil's disease was made in this way. The patient had bathed in the Cherwell four weeks before the illness began—probably too long an interval for infection to have occurred then—but his home was near the river, and rats had been seen there. At this time there were no objective signs of ill health but he was still very easily tired and it was nearly three months before he felt really fit.

Case 3—This patient had also been bathing in the Cherwell. He was sent from a boy's harvest camp with a provisional diagnosis of poliomyelitis. Four days before admission he suddenly developed a severe headache and pains in the legs, and on admission his

temperature was 101°, his eyes were inflamed, and there was albuminuria; the calf and thigh muscles were extremely tender, and the deep reflexes were absent. Weil's disease was immediately suspected, and the blood urea was found to be 74 mg. per 100 ml. For four days he was very ill, but then rapidly became convalescent. The albuminuria disappeared and the blood urea fell to normal; but the sedimentation rate, which was 54 mm. per hour on admission, rose to 96 and remained high. For the next four weeks he felt perfectly well so long as he was kept in bed, but on the 40th day there was a transient recrudescence of fever accompanied by albuminuria. At no stage was he jaundiced, nor did the plasma bilirubin rise above 0.4 mg. per 100 ml.

Case 4.—The fourth patient was an airman, aged 22, who was scratched on the leg by a rat. Ten days later he suddenly felt feverish; he complained of headache and pains in the limbs and began to vomit. His temperature was 102°. The fever and symptoms persisted for seven days, when he was admitted to hospital. On admission his temperature was 101° and the conjunctivae were injected; there were no other physical signs and no albuminuria. Three days later he was afebrile and felt much better, but two weeks afterwards he suddenly developed mistiness of vision and was found to have punctate keratitis.

COMMENT

In each of these four cases the diagnosis was confirmed by agglutination of the *Leptospira icterohaemorrhagiae* by the serum in a titre of 1 in 1600 or higher. Since then we have had a fatal case, with intense jaundice and uraemia, in an Italian prisoner who was employed in draining fields. Hitherto the number of non-icteric cases has been estimated at approximately 50%, though Kramer (1934) of Rotterdam reported 73 cases, of which only 28 developed jaundice, and in cases in which meningitis develops jaundice is more commonly absent than present (Lescher, 1944). The low incidence of jaundice in our series suggests that in the past many non-icteric cases have been missed. We think this would be less likely to happen if the name spirochaetal jaundice was not so misleading and if it was not too exclusively regarded as an occupational disease. Weil's disease should be suspected whenever the sudden onset of fever is associated with headache, pains in the limbs, and conjunctivitis. Albuminuria, a rise in the blood urea, and a high sedimentation rate are also characteristic. Once the cause is suspected the diagnosis is easily confirmed by the specific agglutination reaction. Our cases support the saying, "No jaundice, no death," but emphasize the importance of keeping the patient under observation for several weeks and allowing a prolonged convalescence.

A Case of Fat Embolism

We report a case of fat embolism presenting the unusual features of a delayed onset after operation without any of the monitorial chest signs.

CASE HISTORY

The patient was a prisoner of war, aged 33. In Aug., 1941, he sustained a tangential bomb wound of his right humerus, with a fracture at the junction of the middle and lower thirds. He was admitted to a military hospital on Oct. 5, 1943, with complete non-union of the fracture. There was a well-healed scar on the outer side of his arm, with generalized muscle-wasting, but no evidence of nerve injury.

A bone-graft operation was performed on Oct. 12. The bone ends were freshened and a 4-in. intramedullary bone peg from the tibia was introduced. A complete shoulder spica was applied. At the close of the operation the patient was somewhat shocked, and one pint of fresh blood was transfused. The early post-operative progress was satisfactory. After 12 days he complained of bleeding from his gums and there was purplish bruising round his left knee and ankle. He was given vitamin C; the stitches were removed from his left leg, which was well healed, and he started to get up and sit in the sun.

Three days later (Oct. 27) he was noisy and irrational at night and incontinent of urine; temperature 98°; pulse 80; no cough, dyspnoea, or cyanosis. The stitches were removed from the right arm via a window in the plaster. The wound healed cleanly, though bruising round the left knee and ankle was more marked. Knee- and ankle-jerks were exaggerated; plantar response was doubtful. There was no evidence of any paralysis. The optic disks appeared normal. Intravenous glucose-saline given. Urine: albumin +; sugar + + +; ketones +; fat globules present. Blood sugar, 170 mg. per 100 c.cm.

Next day (Oct. 28) his general condition had deteriorated; temperature 97°; pulse 88. He was kept tranquil only with luminal and morphine. The plaster spica was removed from the back. Examination of the chest revealed moist crepitations at bases only; no sign of consolidation. On the 30th there was a slight improvement. He was quiet all day without a sedative. On Oct. 31 he was rational.

Drip saline was discontinued after infusion of 36 pints in 34 days. His condition then rapidly improved. A new plaster spica was applied on Nov. 2, and on Nov. 3 he started to get up.

Laboratory Investigations.—The blood and urine examinations are best demonstrated in a table, as follows:

Date	Blood Sugar (mg. per 100 c.cm.)	Urine					Casts, Granula and Hyaline
		Albu- min	Sugar	Ketones	Acetone	Fat	
27/10/43	170	+	++++	+	—	+++	—
28/10/43	160	+	++++	+	—	+++	—
29/10/43	150	+	+	+	—	Not tested	—
31/10/43	140	+	Trace	—	—	—	—
1/11/43	140	+	—	—	—	—	—
3/11/43	100	+	—	—	—	—	—
4/11/43	100	+	—	—	—	—	++
13/11/43	—	Trace	—	—	—	—	—
16/11/43	—	—	—	—	—	—	—

The tests employed were: (1) Benedict's test for sugar in the urine (2) Crocilius-Seifert picric acid method for blood-sugar estimation (3) Fat in the urine was demonstrated by staining with Sudan III. Globules of fat varied in size from a few to 30-40 microns in diameter. It was also demonstrated indirectly by the "sizzling test." In this test, adopted by Major J. V. Wilson, R.A.M.C., a loopful of fat-containing urine is burnt in a spirit flame and makes a distinct sizzling, which is very striking compared with that of normal urine. (4) No sputum was available for fat-globule staining.

COMMENT

The glycosuria and blood-sugar level cannot be entirely explained by the intravenous glucose-saline, because, while this was maintained approximately constant, the blood sugar and glycosuria progressively diminished. Also, the glucose was given at the rate of 0.12 g. per kg. of body weight per hour, whereas in the experimental animal it can be injected at a rate of 0.9 g. per kg. per hour before it appears in the urine. The glycosuria would therefore seem to be, at least in part, of renal origin.

Evidence of renal damage is afforded by the presence of albuminuria and casts, and may be assumed to be due to fat embolism of the kidneys. Glycosuria might thus have resulted from a selective renal damage comparable to that caused by phloridzin. If it occurs with any constancy in fat embolism it might be a point of diagnostic significance. It was observed in another case of fat embolism occurring in 2 N.Z.C.C.S. in the Western Desert in Nov., 1942, which at necropsy was proved to have extensive fat embolism of the kidneys and other organs. Albuminuria and ketonuria were present, but the clinical features and other circumstances of the case differed considerably from the one under review.

We are indebted to Lieut.-Col. A. Cruickshank, R.A.M.C., for permission to publish this case.

Torsion of the Gall-bladder

The rarity of the above condition, I hope, warrants its publication; it is the first such case that I have seen in over 30 years of practice.

Miss A., aged 67, in normal health, was reaching up to put a shilling in a slot meter on Feb. 4 when she was seized with acute abdominal pain under the right costal margin. She was not sick and thought it might be appendix trouble, so she starved herself to some extent as her own means of treatment. The pain persisted, and on Feb. 7 she sent for her doctor. At this time the patient had no rise of temperature or pulse rate, and no sickness, but her pain was severe, and a tender lump was palpable below the costal margin.

I was asked to see her on Feb. 8 and found the conditions as above. The patient was transferred to a nursing home on the 9th, and Dr. Shera, the pathologist, kindly did a white count for me, which showed 6,800 leucocytes only. On Feb. 10 I performed a laparotomy, making a Kocher's gall-bladder incision. The transverse colon was adherent to the liver edge; this separated readily with a gauze swab, and immediately the gall-bladder came into the wound with a long pedicle which untwisted easily. It had been lying in a bed formed by coagulated lymph and exudate. I removed the gall-bladder, ligatured the cystic duct with catgut, drained the cavity, and closed the abdomen. The gall-bladder was found to have two medium-sized stones in it, and was tense and full of almost pure blood. There was no infection.

The patient made an uninterrupted recovery, and went home on March 8.

I am greatly indebted to Dr. Downing for allowing me to publish this case, and to Dr. Shera for the blood count.

Eastbourne.

E. WILSON HALL.

CONSTIPATION

Remove the cause as well as the symptoms of habitual constipation with BEMAX ★

Vitamin B₁ deficiency has been shown to be primarily responsible for intestinal atony.

Bemax is not only a rich natural source of this vitamin; it also contains other factors of the B complex. The action of the various elements may well be inter-related in the success of Bemax in treating common constipation.

TETRONOX

TRADE MARK TABLETS BRAND

Hypnotic — Sedative

Enhanced power of barbitone through careful combination with other drugs—reduced toxicity; no cumulative action or injurious effects on circulation, respiration or gastro-intestinal tract. "Tetronox" has a wide field of indications in psychiatry and is furthermore of value in menstrual discomforts, post-operative and post-partum sedation, occupational insomnia, premature waking, etc.

ANAHÆMIN B.D.H.

Ordinary liver extracts, for successful treatment of pernicious anæmia, must be injected in relatively large doses. Thus there is a tendency for the doses given to be somewhat below the desirable level, and, although the dose may be sufficient to maintain a normal blood picture, the risk of the development of subacute combined degeneration of the cord still remains.

Anahæmin B.D.H., being a highly active solution of the hæmopoietic principle itself, is free from this defect.

Doses of Anahæmin B.D.H., adequate for the maintenance of the erythrocyte level and for the prevention or the arrest of cord lesions, are given in small bulk of solution at relatively infrequent intervals.

Details of dosage and other relevant information will be gladly supplied on request.

Reviews

RECORD OF MEDICAL PROGRESS

The British Encyclopaedia of Medical Practice including Medicine, Surgery, Obstetrics and Gynaecology and Other Special Subjects. Medical Progress 1943 and 1944. Under the general editorship of Sir H. Rolleston Bt. (Price 7s 6d each volume postage extra) London: Butterworths and Co.

Having completed the onerous task of editing the *British Encyclopaedia of Medical Practice* Sir Humphry Rolleston continues to issue annual supplementary volumes under the title of *Medical Progress* the fourth and fifth of which he before us. The general plan is to divide each volume into three parts: the first composed of three critical general surveys with special articles on subjects of topical interest, the second on recent developments in drug therapy from the pen of Prof W. J. Dilling, while the third, comprising about three quarters of the whole, is devoted to abstracts alphabetically arranged. This method, though convenient for reference, inevitably leads to repetition. Thus, in the 1943 volume the Rh factor is dealt with in four articles, and as each writer explains the facts in a slightly different way the inexperienced reader may be left rather confused. But of the general value and helpfulness of these volumes there can be no doubt. One is left with a lively sense of our indebtedness to the organic chemist in unravelling the complexity of the chemistry of the steroids and vitamins, and for the rapid multiplication of varieties of sulphonamides adapted to different diseases. Quite appropriately war medicine and surgery bulk large, to which Sir Arthur MacNalty contributes a valuable article on public health in the present war. It is perhaps invidious to try to pick out individual articles, but we were specially attracted by Dr A. W. Spence on endocrinology and Dr Oakley on diabetes. On thyrectomy for myxoedema gravis a very cautious attitude is taken, but we were interested to read that W. G. Millar and T. F. Ross, while inquiring into "thyroid death" established a significantly higher degree of aortic hypoplasia in cases of fatal accident than in the controls. Does this confirm the belief of insurance companies that some individuals are naturally "accident prone"?

A VIEW OF RHEUMATIC FEVER AND CHRONIC ARTHRITIS

Pathology and Therapy of Rheumatic Fever. By Leopold Lichtwitz, M.D. Foreword by William J. Maloney, M.D., LL.D., F.R.S.E. Edited by Major William Cheser, M.C. (Pp. 211, illustrated 64s 6d) New York: Grune and Stratton, 1944.

Prof. Lichtwitz, recognized as an authority on the pathology of function, completed this book only a few weeks before his death. His main thesis is that the mechanism of rheumatic fever is allergic sensitization of the mesenchymatous tissues, especially the vascular system in its smaller and smallest branches and he has put forward a strong case supported by scientific and clinical evidence. He states dogmatically that rheumatism is caused by a sensitization to antigens, protein in nature, usually the product of micro organisms which may be pathogenic or non pathogenic, but may also arise in response to foreign proteins which are not of microbial origin. Although the book bears the title *Rheumatic Fever*, the author includes chronic arthritis, which in many forms he regards as of the same nature, but he draws a distinction between rheumatic and non rheumatic chronic arthritis, the latter he is inclined to consider as a systemic disease with involvement of the central nervous system, especially the vegetative centres. His net is indeed cast so widely that many diseases not usually regarded as rheumatic are brought within it, such as dermatomyositis and lupus erythematosus.

The discussion of some of the chronic rheumatic diseases is of interest and often provocative, possibly because Lichtwitz's method of classification cuts directly across the more usually accepted systems. His description of the types and clinical features of sporadic arthritis and also of skeletal lesions will provoke criticism and other examples might be instanced. There seems at times to be a tendency to fit the symptoms to the theory instead of the reverse. Dr Maloney who contributes an interesting foreword, justly remarks, "The piling of the clinical complexity of rheumatism upon the confusion of

allergy at first served only to add to the bewilderment," but he regards the arguments in favour as convincing. Whether one accepts the thesis presented by the author or not the book is one to be studied by all who are interested in the problem of the rheumatic diseases.

PARODONTAL DISEASE

Parodontal Disease. A Manual of Treatment and Atlas of Pathology. By E. Wilfred Fitch, L.D.S., M.B., D.S. (Pp. 185, illustrated 18s) London: Eyre and Spottiswoode, 1944.

During the last ten years or so a great change has occurred in our attitude towards the group of dental diseases commonly known as pyorrhoea. Too often in the past the dental surgeon and the medical practitioner have advised and indeed demanded the extraction of every tooth in a patient's mouth in order to eradicate a focus of infection. This book describes in detail our present knowledge of the aetiology and treatment of parodontal disease, and shows how with conscientious treatment and hygiene the condition can be cured and the mouth made healthy without subjecting the patient to the distressing ordeal of wholesale extractions. The actual organisms in an uncomplicated case of pyorrhoea are confined to the floor of the minute ulcers on the gum margin, and, as the disease progresses, to the ulcers at the bottom of the pockets and not in the deeper tissues. Therefore the author argues, if the pockets round the teeth can be entirely eliminated, the ulcers allowed to heal, and new healthy and hard epithelium be stimulated to grow, the patient is cured if he will undertake by hygiene and home treatment his part in keeping the gum margins hard and healthy.

The early chapters on the aetiology and pathology of pyorrhoea form a sound basis for the development of a system of treatment which is described in detail and contains much original thought and the aim of which is to promote a firm keratinization of the epithelium of the gum margin by constant friction from the toothbrush and wooden toothpick. The operation of gingivectomy might be described as the "surgery of access" for the wooden toothpick, for until the pockets have been eliminated it is impossible for the patient to carry out his most important routine. There is an excellent chapter on the treatment of acute ulcerative stomatitis which should be of special interest to the medical practitioner, this is directed towards protecting the ulcers by coagulation with chromic acid or with zinc oxide and oil of clove packs. The essence of treatment, in the author's own words, is the constant care and advice and the untiring and patient supervision lavished on every part of the gum margin of every patient from childhood to old age.

Notes on Books

Primer Congreso Nacional sobre Enfermedades Endémico-Epidémicas is a bulky report containing papers read at the Argentine First National Congress on Endemic-epidemic Diseases held in Buenos Aires in 1942. The congress took place under the auspices of the department of pathology and clinical study of infectious diseases of the University of Buenos Aires. The subjects discussed include diphtheria, typhus, brucellosis, scarlet fever, Chagas's disease, hydatid disease, respiratory infections, typhoid fever, and a number of other infectious diseases. It is impossible in the space available to do more than mention the principal topics but this volume should be of interest to all who are concerned with public health and can read Spanish. Papers by Prof. A. Sordelli and other distinguished Argentine contributors are included.

The Public Attitude towards Mental Disease by Dr. Horace Hill is a short pamphlet privately printed (Laverstock House Salisbury, 2s. 6d.) with the object of persuading the public to recognize the desirability of the early treatment of mental disease and urge the advantages of life in a mental home for the patient compared to his struggles in the world outside, where he is subject to unfair competition and persistent misunderstanding. The importance of discharge from the home as soon as the patient is well enough is also stressed and the desirability of encouraging him to re-visit the home after his discharge as he would at a institution for physical disease is pointed out. In this way stigma would be removed and a more rational attitude towards mental illness fostered. We would all probably agree with the principles enunciated in the pamphlet and if no scientific presentation or new ideas are expected it may be found useful for distributing to patients' friends.

Col. C. A. WEBSTER's vade mecum entitled *Regimental M.O.* contains little to criticize and much to commend. By combining brevity with a free and intimate style the author has managed to cover an amazingly wide field. Apart from its obvious value to the newly commissioned, many medical officers with long experience will welcome a handbook of convenient pocket size, reference to which may save wearisome search in A.M.S. Regs. or Standing Orders, R.A.M.C. The booklet is published at 2s. 6d. by A. Wheaton and Co. Ltd., Exeter, and royalties derived from its sale will go to the R.A.M.C. Comforts Guild.

Preparations and Appliances

REDUCTION OF LEG FRACTURES BY HYDRAULIC TIBIA TRACTION

Dr. J. E. STANLEY LEE, F.R.C.S.Ed., medical superintendent, New Cross Hospital, Wolverhampton, writes:

In fractures of the tibia and fibula overriding of the fragments is extremely common owing to sliding in oblique and spiral fractures, and considerable difficulty is experienced in correcting the displacement and in maintaining good alignment. Manual reduction is often unsuccessful and, if swelling is marked, redisplacement occurs even despite a well-applied plaster unless continuous traction is also employed. In the new method here described reduction is accomplished by hydraulic tibia traction with the aid of an operating table equipped with an oil-pump base. Though primarily intended for skeletal traction, the method can also be used with strapping extension where displacement is slight or moderate.

Description of Apparatus

The apparatus employed consists of:

- (a) An operating table equipped with hydraulic raising mechanism (Fig. 1).
- (b) A thigh support (Figs. 2 and 3) in the form of a half-section of a truncated cone 10 in. long, made of sheet metal suitably padded,

FIG. 1

FIG. 2

FIG. 3

FIG. 4

FIG. 5

having a proximal diameter of 7½ in. and a distal diameter of 6½ in., and attached to a strong base with an angled extension piece which passes round the edge of and below the table, to which it is fixed by a screw clamp operated by means of a sliding Tommy bar. At the proximal end the sides are cut away to enable the thigh rest to be used for adolescents and children. Chrome leather pads are fitted to the upper surface of the clamp and to the under aspect of the thigh support. The sliding Tommy bar provides good leverage, enables the apparatus to be rapidly fixed in position, cannot become detached, and can be pushed out of the way so as to allow ample room for the surgeon's hand and the passage of plaster bandages. The space available between the edge of the apparatus and the back of the leg is not less than 4½ in. The thigh rest incorporated in Watson-Jones's (1932) tibia traction apparatus, of which the above is a modification, can be used.

(c) A tensometer spring (Fig. 1) graduated up to 100 lb., as used by Farquharson (1942).

(d) A hook let into the floor (Fig. 4) or, alternatively, an inverted enamelled bowl filled with lead, with a hook inserted through the bottom of the bowl into the lead filling (Fig. 5), which in the case of a bowl of 10 in. diameter weighs approximately 75 lb.

Method of Reduction

A Kirschner wire (or other form of traction pin) is driven through the tibia 1 in. above the ankle-joint, and a stirrup is fixed to the wire (or pin). Next the tensometer spring is hooked to the stirrup and, at its lower end, attached to the hook in the floor (or weight) by a short length of cord (Fig. 1). The thigh is thus supported on the rest with the knee flexed to a right-angle and the limb hanging vertically in the line of gravity, in which position there is no tendency for the fragments to sag backwards, and while the plaster is setting the position of the foot can be controlled by the operator's knee and lateral displacement of the fragments corrected by his hands.

An assistant gently operates the foot pedal attached to the oil-pump base of the operating table while the tensometer spring and cord are held in position until tension is felt. Further elevation of the table by the assistant results in hydraulic traction being applied in the line of gravity. The limb becomes taut, and when the overriding has been fully corrected crepitus is felt by the operator, indicating that the fragments are now in apposition and traction is such that angulation is also corrected. Rotational displacement cannot occur if the axis of the wire is correct, and the toe and the patella consequently point in the same direction. The fragments are then locked against each other by strong lateral pressure of the operator's two hands. This is an essential step, without which accurate reduction cannot be accomplished. So strong is the traction that very firm lateral pressure is necessary. Antero-posterior and lateral radiographs are taken and, if position is satisfactory, plaster is applied.

Application of Plaster

A plaster-of-Paris slab is placed directly to the skin over the posterior aspect of the limb from the back of the knee to the toes passing through the stirrup. A thin pad of wool is placed in front of the ankle-joint; but if swelling has not yet taken place it may be advisable to use a thin wool bandage over the front of the foot and leg before the plaster case is completed by encircling bandages. While the cast is setting, strong lateral pressure is again maintained by the palms of the operator's hands, and as soon as the cast is hard traction is released, the knee straightened to 30 degrees short of full extension, and the plaster case then extended to mid-thigh.

Subsequent Treatment

In all unstable oblique and spiral types of fractures continuous traction is necessary for the first three to six weeks. The limb is supported on a Braun splint, and 10 to 15 lb. of weight suspended over the pulley, with the foot of the bed raised about 12 in. When swelling has subsided a new plaster case should be fitted. The limb is again held in the hydraulic tibia traction apparatus and the new plaster applied, completely unpadded, from the toes to just below the groin with knee-joint slightly flexed. When the plaster is set the Kirschner wire is removed. Radiographs are taken in two planes, and if alignment is not absolutely accurate it should be corrected by wedging the plaster case.

I am deeply indebted to the writers of Mr. R. Watson-Jones (1932) for which I have drawn freely and at length; to the Wolverhampton Borough Surveyor's Department for the illustrations; to Messrs Guy Motors Ltd., Wolverhampton, who generously made the thigh support to my design for me; and to Mr. McGowan for the weight. Messrs Down Bros., Ltd., London, have kindly undertaken to manufacture and supply the complete apparatus.

PROBLEMS OF ARIBOFLAVINOSIS

We print in this and last week's *Journal* an abridged form of the Lumleian Lectures of 1944, given by Dr. Hugh Stannus, who took as his subject riboflavin and allied deficiencies. From a survey of the recent literature it would at first seem that the syndrome characterizing riboflavin deficiency was unknown before 1938, when Sebrell and Butler¹ induced the condition experimentally in a group of women in an institution by feeding them on a diet low in riboflavin. They suggested the name ariboflavinosis for riboflavin deficiency, and although they established that lack of riboflavin gives rise to a definite clinical picture they were not the first to describe it. The essential clinical features of riboflavin deficiency were in fact first described by Stannus² over thirty years ago, when he was working among the natives of Nyasaland. His observations made in 1911 were published in 1912 and 1913. It is a sad reflection on our colonial administration that these studies should have been made in one of our Colonies in the days of prosperity before the last war; regrettable that little was done to remedy the defective nutrition of these African natives; and disappointing that only recently has the work of Stannus received the recognition it so well deserves. Twenty years before the discovery of riboflavin he described the ariboflavinosis syndrome—the sore tongue and lips, the sodden excoriated palpebral fissures and angles of the mouth (which he termed angular stomatitis), and the characteristic lesions of the anus and external genital organs. He also described certain neurological features and the characteristic smooth red tongue devoid of papillae and epithelium, known later among American workers as the "magenta tongue." While the contemporaries of Stannus believed that these lesions might be infective in character, he thought that they were the result of dietary deficiency. Beyond this he could not go, as the vitamins, though postulated by Funk in 1912, had not then been differentiated and the existence of riboflavin was quite unknown. The importance of this early work of Stannus lay in the fact that he focused attention on the occurrence of this group of symptoms due to a dietary deficiency yet dissociated from pellagra. In the Lumleian Lectures he reviews the work published before that of Sebrell and Butler in 1938. He pays tribute to Fitzgerald Moore, another worker who laboured for many years trying to defeat malnutrition in the Colonies. To Moore belongs the credit of showing that the disease which was rendering thousands of African natives nearly blind was due to a dietary deficiency and amenable to treatment with a yeast extract. In a series of papers between 1930 and 1939 he described certain

ophthalmological conditions and nervous symptoms which Stannus thinks may have been due to riboflavin deficiency.³

Some doubt has recently been cast upon the validity of angular stomatitis and corneal vascularization as manifestations of riboflavin deficiency. Stannus believes that angular stomatitis is characteristic of the condition, though many workers believe that it is not a specific lesion. Thus it is stated to occur as a result of badly fitting dentures,⁴ local trauma, and sensitivity to the constituents of chewing-gum⁵ and lipstick.⁶ Machella and McDonald⁷ failed to improve a series of cases of angular stomatitis by treatment with riboflavin, though some responded to nicotinic acid, vitamin B₆, and yeast. Smith and Martin⁸ also observed that angular stomatitis may disappear after the administration of vitamin B₆. Stannus believes that these lesions can be distinguished from the characteristic angular stomatitis of ariboflavinosis, or, as he prefers to call it, hyporiboflavinosis. Even so, a diagnosis of ariboflavinosis should not be made on the existence of stomatitis alone. Considerable discussion has centred around corneal vascularization as a manifestation of ariboflavinosis. Sydenstricker and his co-workers,⁹ who drew attention to this sign in 1940, regarded it as pathognomonic of ariboflavinosis and stated that circumcorneal injection, which precedes it, is the earliest and commonest sign of the condition. There appears to have been some subsequent confusion between the terms circumcorneal injection and corneal vascularization. The former is an engorgement of the bulbar conjunctival capillaries of the limbic plexus: the latter is actual invasion of the cornea by capillaries which anastomose to form tiers of capillary loops from which more capillaries develop and extend centripetally. Stannus, who has carried out between 4,000 and 5,000 slit-lamp examinations and is, therefore, qualified to speak on the subject, states that he has seen both circumcorneal injection and corneal vascularization without any evidence of riboflavin deficiency, and that these signs alone are therefore of no diagnostic value in the detection of the deficiency. He agrees that they may occur in patients with riboflavin deficiency, but denies that they are pathognomonic of the condition. His experience confirms that of a number of other investigators who have carried out nutrition surveys during the last two or three years, and have shown that corneal vascularization is fairly common in the population at large in the absence of nutritional deficiency. Sanderstead,¹⁰ for example, found that the incidence of the condition ranged from 80 to 93% in the groups he studied.

A number of workers in the English colonies, including Fitzgerald Moore,² Scott,¹¹ and Landor and Pallister,¹² who all wrote before the recognition of ariboflavinosis as a clinical syndrome, described certain neurological symptoms which did not fit into the clinical picture of beriberi or pellagra. These included burning of the feet, muscular

weakness, ataxia, incoordination, paraesthesiae, and loss of visual and auditory acuity. Stannus accepts these symptoms as manifestations of ariboflavinosis, particularly "burning feet," which he believes is a characteristic neurological finding. To these symptoms he adds others which he has observed. They fit into a condition resembling the cerebellar syndrome—muscular asthenia and hypotonia, jerky clonic contractions, nystagmus, tremor, dysidiadokinesis, a typical gait, and pendulum knee-jerks. It is interesting to note that American workers, who have contributed the bulk of the literature on ariboflavinosis since 1938, do not mention any neurological manifestations. They describe diminished visual acuity, which might be the result of retrobulbar neuritis.

No satisfactory theory has so far been put forward to explain the pathogenesis of the signs and symptoms of riboflavin deficiency and their peculiar localization. Why are the mucocutaneous junctions of the mouth, eyes, and anus selected? Why is the tongue affected? Why do the nervous symptoms resemble the "cerebellar syndrome"? Stannus has advanced a novel theory based on anatomico-physiological considerations to explain these varied lesions. He believes that they are a manifestation of an acute functional derangement of the capillary circulation of the affected parts. The first tissue to suffer from riboflavin deficiency is the endothelium of the capillary system, which needs riboflavin for its nutrition. The capillaries undergo a reversible functional disturbance, a capillary dysergia, resulting in loss of tone and dilatation. Normal cellular metabolism is upset and tissue functions are disturbed. The first parts to suffer are those with the largest numbers of capillaries, those with the greatest metabolism, and those with a very specialized function. The interference with tissue-cell metabolism is probably of the nature of an anoxia, using this term in its widest sense. If the anoxia is not too prolonged recovery of function takes place in the capillaries when supplied with adequate riboflavin; otherwise irreversible processes leading to pathological changes occur. According to Stannus skin lesions of ariboflavinosis, which occur where the skin is thin or highly specialized, as at the mucocutaneous junctions about body orifices (lips, palpebral fissures, nostrils, prepuce, vulva, anus, scrotum), are due to capillary congestion, with resulting impaired nutrition of the skin. The colour of the "magenta tongue" of ariboflavinosis is the result of capillary dilatation and a sluggish blood flow. While Stannus grants that the changes in the cornea are due to riboflavin deficiency, he believes that the visual disturbances associated with the latter have no immediate connexion with the eye but are part of a lesion in the central nervous system. The neurological manifestations, says Stannus, are the expression of a metabolic disturbance in nerve tissue produced by capillary dysergia, the more vascular tissue being the first to suffer—i.e., the grey matter and cerebellar neuropil.

Any satisfactory theory of the pathogenesis of ariboflavinosis, particularly one involving the capillaries, must be based on histopathological findings. From the pathologist's point of view, if not from the clinician's, it is disappointing that no cases of human riboflavin deficiency have come to necropsy so far. Studies with the dermal

capillarscope in the living might help to support theory of Stannus. It has been shown with the use of this instrument that there are capillary changes in the skin in pellagra.¹³ A microscopical study of the skin of subjects with riboflavin deficiency might yield interesting results.

THE "TRIPLE" AND THE "CONJOINT"

If effect is given to the recommendation of the Goodenough Committee that every medical school should be an integral part of a university, one school in London and three in Scotland will either cease to teach or undergo absorption. The West London Hospital Medical School is the last in the field of undergraduate medical education; it was opened in 1937, and in the session 1942-3 it had 38 students, all women. The decision on its application for admission to the University of London was deferred pending a general review of the provision for women students. The Goodenough Committee is of opinion that an increase in the number of University of London schools cannot be justified, and that, important as the contribution of this school to the training of women students has been, it should not continue its undergraduate work beyond possibly the next four or five years.

The three Scottish schools have a different background. The Anderson College of Medicine in Glasgow was established as part of "Anderson's University" in 1795. John Anderson, professor of natural philosophy and friend of James Watt, endowed the school with a meagre legacy out of keeping with his rather grandiloquent prediction for it; but it struggled on and prospered, and came to have more teachers than the University of Glasgow. Later its medical side was separated from the other departments of technology and given its own domicile and governing body. The second school, St. Mungo's College, Glasgow, owes its origin to the steps taken to rehabilitate the Royal Infirmary after the severe blow it received when the University was removed to the west side of the city and the Western Infirmary built alongside. The Royal Infirmary School of Medicine, for which a charter was obtained in 1889, became St. Mungo's College. The third school, that of the Royal Colleges of Edinburgh, consists of lecturers licensed by the two Colleges and in most cases recognized by the University. It is a single corporate body governed by a board. In the last academic year for which figures are available Anderson College had 252 undergraduate students, St. Mungo's 339, and the School of Medicine of the Edinburgh Royal Colleges 359. From these three schools the majority of the candidates for the Scottish triple diploma are drawn.

Extramural teaching—there were other schools of the kind which flourished in Glasgow for a short time in earlier days—has played a great part in Scottish medical education. The rostrums of these schools attracted teachers of eminence, especially the great anatomists. The schools were able to parallel the courses in the University; their fees were lower, and they offered opportunities for teacher and taught which the more rigid methods of the University

denied. But university teaching itself altered and widened. A large increase took place in the number not only of professors but of departmental lecturers and assistants, and facilities were offered for research, so that the abler of the young medical graduates tended to seek appointments in the University rather than in the extramural schools. The tendency is all towards integration with the University, with its liberal atmosphere and intellectual stimulus and the contacts it offers with other learning. If in this process extramural teaching disappears it is an evolutionary development and takes nothing from the lustre of the past achievement of these schools.

In another direction the Goodenough Committee suggests further concentration upon the university. In urging that the University of London—and this also applies in a measure to Oxford and Cambridge—should reconsider the standard of its final examination, introducing "internal" features bringing it more into line with its teaching and holding the examination more frequently, also that university grants to schools might be conditioned by the number of students taking the university degree, the Committee is obviously placing the English Conjoint Board examination in some peril. The history of the "Conjoint" goes back to the latter part of the nineteenth century. In 1873 we find the Medical Reform Committee of the British Medical Association expressing satisfaction with steps taken to form a Conjoint Examining Board for England, but it was not until ten years later that the two Royal Colleges agreed that a diploma be granted in conjunction on the results of the final examinations held on their behalf by the Examining Board. Thereafter the licence of the Royal College of Physicians and the diploma of membership of the Royal College of Surgeons were no longer granted separately as qualifying for admission to the *Register*. The conjoint examinations in England and also those in Scotland (by the Colleges of Physicians and Surgeons of Edinburgh and the Faculty of Physicians and Surgeons of Glasgow) were approved by the General Medical Council in 1884. The Medical Act, 1886, laid it down that a qualifying examination might be held for the purpose of granting a diploma conferring the right of registration by "any combination of two or more corporations in the same part of the United Kingdom who may agree to hold a joint examination in medicine, surgery, and midwifery, and of whom one at least is capable of granting such diploma as aforesaid in respect of medicine and one at least is capable of granting such diploma in respect of surgery." The Conjoint Board examinations in England have proved very popular, especially among London students, owing to the attractive alternative they offered to the London University Final M.B. B.S. which is out of line with the teaching of the school and is a stiff "external" examination, reminiscent of the days when the university was an examining body only. The "Conjoint" enables Oxford and Cambridge students to qualify a year earlier than they can do by taking their university degrees. Of the practitioners who qualified from London schools in 1933-7, 2,414 were registered on their diploma of the English Conjoint Board, and only 192 on a university degree, though it should be added that a university degree was obtained later by about

one third of them. From the other universities 414 were registered on the Conjoint diploma.

One incidental result of a decline in popularity of the Conjoint examination would be a diminished revenue of the Royal Colleges. The amount which the Royal College of Surgeons received from the Conjoint Examination Board in 1942-3 was £11,168—more than half the total income of the College. But it is not to be disputed that competition between the university and the Conjoint Board examinations is educationally bad, and that a university examination ought to be regarded not as something separate from the student's record during his course of training but rather as a final check upon it. If, again, as in the case of the extramural schools, the portended changes in medical training threaten the numerical pre-eminence of the "Conjoint," no reflection will be conveyed on the diploma, for it is agreed that the examination is of good vocational standard, only slightly different from that of the university, and with the same subjects.

SURGICAL TREATMENT OF CORONARY DISEASE

It is now some seven years since surgeons first attempted to provide a new blood supply for the heart which was being starved by progressive coronary sclerosis. Claude Beck was a pioneer in this field of surgery in America, and in two recent papers he and his physician colleague Harold Feil review the results of the past few years.^{1,2} It appears that there have been few new discoveries or startling improvements in technique. Some might have come from this country had it not been for the early death of Laurence O'Shaughnessy, whose operation of cardio-omentopexy had already given promising results.

During his experimental work on dogs Beck observed that the gradual reduction of the blood supply to a small area of the heart, by ligation of the arterial branches supplying the area, results in a "trigger" mechanism. When a certain degree of anoxaemia has been reached further slight reduction in the blood supply causes sudden ventricular fibrillation and death. In contrast two of the main coronary arteries may be partially occluded, producing a less degree of anoxaemia over a larger area, without causing death. Beck draws two conclusions from these observations: first, that acute anoxaemia of a small part of the cardiac muscle can act as a trigger or irritable zone which may throw the whole mechanism into the convulsions of ventricular fibrillation, and second that a very small improvement of the blood supply to the irritable zone can reduce its irritability and prevent it from "firing". The blood supply to the heart can be increased by effecting communications between the coronary vessels and other arteries outside the heart—for instance by grafts, or by producing intercoronary anastomoses. The coronary arteries communicate very little with one another, but inflammation on the surface of the heart produces anastomotic channels between them. Beck showed that ligation of the descending ramus of the left coronary artery in normal dogs caused death in 70% of cases, but when the surface of the heart had previously been abraded to set up inflammation and adhesions the mortality after ligation of this vessel was only 38%. Beck's operation aims at producing inflammatory adhesions between the heart and

¹ *Lancet*, June 1943, 1118-1133.
² *Ibid.* p. 807.

the parietes by applying powdered asbestos to the surface of the heart and by laying grafts of mediastinal fat against it. His illustrations demonstrate conclusively that vascular channels are formed in such adhesions, both in animals and in man.

Unfortunately the results of this procedure are not encouraging. Feil describes 37 patients treated by the Beck operation: there were 14 operative deaths, and 23 survived. Of the latter, 14 were improved and are still living, 9 died within four months to six years of operation, all from coronary disease, and 5 of these experienced relief of their symptoms. Patients with severe coronary disease rarely survived the operation, and those that did survive were unimproved. Therefore the early case with only slight myocardial damage should be chosen for operation; but even in the later cases of the series, when such selection was being applied, the operative mortality was 35%. Grave as is the prognosis of coronary disease, such a mortality will discourage most physicians from submitting their patients to this hazard. Nevertheless there is now considerable evidence that these operations do, in most cases, reduce the severity of the symptoms and even prolong life if the patient can survive the initial shock. It is therefore to be hoped that future improvements in technique will lower the operative mortality. There is certainly scope for more research in this field.

HEALTH RECORD OF THE U.S. ARMY

The Surgeon-General's statistical report for 1943, circulated by the U.S. Office of War Information, gives some interesting facts and figures. The number of men examined during the year was 5,200,000; the number recruited into the Army was 2,400,000, and into the Navy, Marine Corps, and Coast Guard 900,000; the number rejected was 1,900,000 (36%). The Army certificate-of-disability-for-discharge rates have run rather high. The majority of such discharges occurred within the first three months of service, suggesting that mental and physical defects were missed at the medical recruitment examinations. The health of the U.S. Army has been better than it was at any time during peace. Up to the end of 1943 only 3% of the wounded had died of their wounds. The Army's over-all death rate from disease was 0.6 per thousand per annum, this despite the fact that American soldiers are fighting on all fronts, in all climates, and exposed to all diseases. The death rate for pneumonia before the advent of sulphonamide drugs was 24%; the present Army death rate is 0.7%. The death rate from meningitis, which forty years ago killed 80% of those contracting it, was reduced to 38% in the last war and, through the use of "sulpha" drugs, has now fallen to 4.2%. The admission rate for tuberculosis has declined from 12 per thousand per annum in the last war to 1.2 in the present war. The programme for recruitment of individuals with venereal disease was officially inaugurated in October, 1942. Special V.D. hospitals were built at each of the 34 reception centres, with a total of 6,510 beds. Recruits having venereal disease were referred to these hospitals, where they were examined and treated. The U.S. Army is vaccinated against smallpox, paratyphoid, typhoid, and tetanus. Typhoid fever, which was the scourge of armies until 1912, has been reduced to insignificance. There have been no deaths from typhus, though this disease is endemic in North Africa. There has been no tetanus in the vaccinated, and vaccination against yellow fever has prevented any incidence of this disease. Vaccination is available when there is danger of exposure to cholera and plague. Against the

menace of insects as carriers of disease the sanitary service has developed the Freon pyrethrum bomb which, upon the turning of a spigot, will spray a plane or tent or barrack killing all flies, mosquitoes, and bed-bugs in the area treated. This spray is non-toxic to man. The synthetic compound, known as "DDT" (dichlorodiphenyltrichlorethane) has been introduced for killing lice; the use of this powder (which is also effective against flies) enabled the United States Typhus Commission to prevent the development of an epidemic of typhus fever in Naples. The report on the dental service states that rejections for dental defects ran to around 5%. It was decided then that if a recruit had no malignant disease or extensive osteomyelitis in his jaw he would be accepted regardless of the number of serviceable teeth. This threw an immense load upon the Army Dental Corps. During the years 1942 and 1943 14,600,000 cases were treated, and 31,000,000 teeth were filled; more than 1,400,000 bridges and dentures were supplied, 196,000 dentures mended, and more than 6,000,000 teeth replaced by dentures and bridges.

MEDICAL FILMS

There should be plenty of room for the use of the moving film in medical education. If anyone had doubts on this subject the viewing of the two films recently made by the British Council should have removed them. The moving picture tells a story that often enough can be told with poor effect in words only. In fact there is always the risk that the word will accumulate many meanings remote from what it stands for. One such word is "rehabilitation," which at the moment is in danger of almost becoming a political slogan. The recent British Council film, "Accident Service" (see *B.M.J.*, June 10, p. 789), made it vividly plain to all and sundry just what rehabilitation is. We can think of no better way of informing the medical student of what rehabilitation is than by showing him this film. It is even possible that the film will teach more than a visit to such a centre as Berry Hill Hall, because the film is the product of many minds, and gathers up into one whole all the numerous links in the medical and surgical chain that rehabilitates the injured or diseased person. But films can become an educational force in medicine only if they are well done, and they can be well done only if the expert film technician and the expert medical technician are given a free hand to work out their common problem on an equal footing. The film technique should be as good of its kind as the medical or surgical technique; if the student's mind is to be satisfied. Until the perfect library of medical films can be formed we must rely upon the slightly imperfect copies that owe their existence usually to the enthusiasm of amateur medical cinematographers. Full use of the films that now exist can be made only if they are fully catalogued and classified by some central organization. Recently the Scientific Film Association set up a medical standing committee "to further the production and distribution of medical films suitable for circulation within the medical profession, either for training and teaching purposes or for the general dissemination of information." After the war it is hoped to set up a central medical film library, and as a step towards this any doctors who know of or have medical films are asked to inform the secretary of the Medical Standing Committee, Dr. S. J. Reynolds, 14, Hopton Road, Streatham, S.W.16. So that the information about each film may be systematically assembled a questionnaire has been drawn up by the Scientific Film Association which will be sent to any inquirer. Ordinary membership of the Scientific Film Association is open to anyone interested in the subject.

SOME COMMON PAEDIATRIC PROCEDURES A REASSESSMENT FOR CHILD WELFARE PRACTICE*

BY

DOYNE BELL, D.M.

Physician, Belgrave Hospital for Children; Physician in Charge of Children's Department, Queen Mary's Hospital for the East End

It has seemed to me suitable, in addressing this audience, to confine my remarks to such aspects of the subject as are the day-to-day concern of the worker in the child welfare clinic. The choice of a few points of common paediatric procedure for your reconsideration has therefore been based on cases referred to me from welfare centre practice or presented as problems to midwives and students in maternity departments. If, then, my conclusions seem to many to be self-evident, I must plead that to others they have seemed less obvious.

The Crying Baby

Handbooks on the care of babies quite rightly tell their readers that the treatment of the crying baby is to find out the cause of its crying and correct it; yet in practice it is not at all uncommon for mothers to complain that their babies cry for hours on end, and an examination of such babies shows no abnormality to account for this behaviour. Endless and apparently motiveless crying is extremely disturbing to the mother, and may result in such anxiety that lactation fails. Even without such a serious consequence the symptom is distressing both to the baby and to all who hear it, and calls for treatment. I think in many cases, though the crying was started by some momentary discomfort, its persistence is due to the discomfort occasioned by the crying itself. The baby gets hot and its pillow wet, and so the crying continues. In these cases, after excluding by thorough examination an organic cause of pain, the giving of a sedative is amply justified. It is important, however, to give it in sufficient dose to ensure that the habit of crying is broken. Nothing discourages the mother more than to be given a medicine which she hopes will soothe the infant and then to have her hopes frustrated. For an infant 6 months old, for instance, phenobarbitone, gr. 1/2, would be an appropriate dose. The sedative need not be repeated for more than three or four nights as a rule.

Breast-feeding

The commonest errors in the handling of the breast-feeding of the newborn child seem to be due to anxiety and pessimism—anxiety lest the newborn infant should be underfed in the early days of life, and pessimism with regard to the mother's ability to suckle her child. Admittedly the factors influencing lactation are incompletely understood and complex—too complex for detailed discussion here; but it is clear that successful breast-feeding does not depend entirely on mechanical factors such as the stimulation of the nipple by sucking and the emptying of the breast. Endocrine influences of much complexity play an important part, and anxiety or pessimism or a display of even cheerful ignorance by nurse, doctor, or health visitor will often effectively disturb what should be a normal lactation. My plea, therefore, is for a much more intelligent and intensive field study of lactation. Such study would show, among many things, how great is the variation in the appetites of normal newborn babies and in the time taken for lactation to become established. I am depressed at the number of infants discharged from maternity hospitals at the age of 2 weeks or less, wholly artificially fed. Often in such cases I learn that on or about the tenth day after delivery the mother has been given tablets to dry up her milk and told that she has an insufficient supply. There is nothing pathological in the fact that on the tenth day the supply of breast milk is less than 2½ fl. oz. per lb. of the infant's body weight. I think it is a fair generalization to say that, in the case of a healthy mother and infant, it is never possible in the first three weeks to state that lactation will not be established and should be abandoned. I have made it a rule, in a midwifery department where the newborn babies are in my care, that no infant is ever to be given a complementary feed (I except water and saline) without my being notified. As a result such feeding is, in normal cases, practically unknown.

In contrast let me instance a case referred to me last year. A mother aged 20 was sent with her 9-weeks-old infant to see me because he was restless and crying, and vomited. The baby had been born in a private nursing home, and had never been put to the breast. The mother had been purged and had her breasts bound up on the third day, and a variety of proprietary foods had been given to the infant. On examining the mother's breasts I found that a few beads of milk could be expressed. She was obviously disappointed that she had been thought incapable of suckling her child. I gave her the ordinary advice for re-establishing lactation,

but warned her not to be unduly depressed if she failed. She wrote 44 weeks later to tell me that her infant was fully breast-fed. The indiscriminate use of synthetic oestrogens has of course made the re-establishment of wrongly abandoned lactation more difficult.

The study of natural lactation can be carried out only by the paediatrician who sees the baby from birth onwards. The time available to the obstetrician or midwife—two or three weeks as a rule—is too short for a proper study to be made. This, incidentally, is a further argument, if one is still needed, for the paediatric supervision of the newborn babies in maternity units. The premature termination of lactation, like the termination of pregnancy, is a step which may have serious consequences, and should never be undertaken without a full knowledge of the factors involved and a careful consideration of the medical indications.

The formation of an abscess in the lactating breast is a complication of breast-feeding that needs much study. There is apparently a widespread failure to appreciate the aetiological factors and what should be the aim of treatment. Most cases of suppurative in the lactating breast are preceded by obstruction of the milk ducts, producing a tender, knotty breast. Treatment of this condition and prophylaxis of abscess formation should clearly aim at removing the obstruction and re-establishing the milk flow. Taking the baby off the affected breast and tight bandaging are therefore to be condemned.

When an abscess has definitely formed it is still too often forgotten by the surgeon that he has two patients—the mother and the infant. No treatment of breast abscess should be considered entirely satisfactory which does not achieve as its end-result normal lactation. A fissure in the nipple should be considered a danger signal, for it may be a portal of entry for infection to the deeper breast tissues. In any event, the fissure itself is extremely painful and may render breast-feeding from the affected side temporarily impossible. If, on account of pain, breast-feeding has to be suspended, particular care must be taken, while the fissure is under treatment, to prevent milk engorgement of the breast, either by manual expression or by the use of the breast pump. The objects of local treatment of the fissure are disinfection and rest, just as if it were an ulcer anywhere else in the body. There are many ways of achieving these ends, but a very practical method, and one that gives rapid relief of pain, is the application of a lead nipple-shield between feeds.

Artificial Feeding

The technique of artificial feeding should be elastic and be modified to suit the individual infant's requirements, and in this important branch of paediatrics rule-of-thumb methods have little place. One not uncommonly sees infants suffering from dietetic upsets who have been treated by many changes of the brand of dried milk offered but none in the composition or quantity of the food. The only change has been in the branded name on the tin. The slavish belief in the advertised merits of proprietary brands of dried milk has interfered with the wider use of national dried milk. In this respect some hospitals have been much to blame. An infant is admitted to hospital and fed on a proprietary brand of straight full-cream dried milk; if he does well the mother is naturally reluctant to change to national dried milk when the infant returns home. Thus she pays at the chemist's shop three or four times as much as she would pay for the identical product at the food office or clinic.

Respiratory Infections in Childhood

Chronic nasal discharge in small infants with resulting snuffles or nasal obstruction is a very common symptom. The origin of these snuffles is probably a mild catarrhal infection of the nose, but the persistence of the symptom is often due to mistaken attempts to clear the nose with pledgets of cotton-wool. These pledgets are useless for the purpose for which they are intended, and the delicate mucous membrane of the infant's nose is always irritated and often injured by their use, and a chronic infection results. Most cases of snuffles will clear up when the use of such pledgets is discontinued.

Whether tonsils should be removed or not is a question asked frequently in welfare centre practice. It clearly requires careful and individual consideration. No one who has seen some of the bad results of indiscriminate tonsillectomy will fail to realize the importance of a right decision. The tonsil undoubtedly plays a large part in the defence of the respiratory tract of the young child against infection, and its removal while still capable of healthy function will only weaken the defence. I do not think it is an over-simplification of the problem to state that there are but two indications for the removal of the tonsils in children under 5 years old. The first is hypertrophy of the tonsil to a degree which interferes with the child's swallowing; the second is chronic infection of the tonsil, resulting either in repeated auto-infection of the respiratory tract or in the child's becoming a carrier of pathogenic organisms which cannot be eliminated by other means. It is important to remember that a history of repeated acute infections in the child is not necessarily an indication for removal of the tonsils. The repeated infections may be due simply to repeated exposure to an outside source of infection. The same principles

* Lecture (abridged) given in London to the Maternity and Child Welfare Group of the Society of Medical Officers of Health.

should be applied to consideration of the removal of adenoids. The adenoids should be removed if they are the site of chronic infection, or if their hypertrophy obstructs the nasal air-way or interferes with the drainage of the paranasal sinuses or middle ear.

In the prophylaxis of respiratory infection in childhood it is still not uncommon to find that clinics are exposing children to ultra-violet light. The uselessness of this procedure was well shown by Dora Colebrook as long ago as 1929. She studied three groups of children, of which one was exposed to ultra-violet light, another to a screened lamp from which no ultra-violet rays came, and the third served as a control. She found no significant difference in the incidence or duration of respiratory infections in the three groups; the very small and insignificant difference being favourable to the control group. In the absence of any work to contradict these findings it seems to me that the exposure of children to ultra-violet light is quite unwarranted.

Strawberry Naevi

The strawberry naevus or capillary haemangioma is quite a common birthmark, and a great number of cases are still referred to hospital, often with the suggestion that they should be treated with CO₂ snow, with radium, or by excision. The natural history of these naevi was studied by W. A. Lister (1938), and he found, in a series of 77 children with 93 naevi who were watched for periods varying from one to seven years, that there was no exception to the rule that naevi which grew rapidly during the early months of life subsequently retrogressed and, of their own accord, disappeared, on the average at about the fifth year.

My experience is in accordance with Lister's findings. Any form of treatment is bound to leave a scar, whereas natural retrogression of the naevus leaves normal healthy skin. The chief difficulty in practice is to persuade the child's mother that the naevus will retrogress after reaching its maximum size at the age of about 12 months. My practice is to make an exact tracing of the naevus on a piece of "cellophane" or washed x-ray film and transfer this pattern to paper. This paper is dated and given to the mother to keep. She may then observe for herself that the naevus does not further increase in size, but gradually shrinks or fades. In many cases the retrogression starts in patches in the middle of the naevus, but after the age of about 12 months the edges, even if they are the last bits to disappear, do not spread.

Circumcision

This mutilation has a long history which is of great anthropological interest. But its popular justification on hygienic grounds seems to be of quite recent origin and of extremely doubtful validity. As it is not free from hazard and discomfort it is well, when considering it as a surgical procedure, to take stock of the indications for the operation. So far as I know, there is but one—phimosis; this being defined as a stenosis of the preputial orifice which prevents retraction of the prepuce behind the corona of the glans penis. In most cases in which circumcision is performed no attempt is made to assess whether phimosis is present or not; for normally the prepuce of the infant is lightly adherent to the glans, and it is these adhesions which prevent retraction. If the adhesions are divided—and this can easily be done either by digital retraction or with a probe, though I do not suggest that it is a desirable routine procedure—it will be found that phimosis is rare. If the preputial orifice is smaller than the urinary meatus—an extremely rare occurrence—interference with urination will occur and operation is certainly necessary. But I doubt whether operation is indicated in degrees of phimosis in early infancy. Indeed, it has been noted that some degree of phimosis, as above defined, is normal in young infants.

I have heard it suggested that a long and inflamed prepuce or the so-called "cauliflower prepuce" indicates circumcision. This condition is in fact an absolute contraindication to circumcision. The "cauliflower prepuce"—the site of cellulitis, oedema, and even ulceration—is the result of an ammonia dermatitis. To remove such a prepuce is to expose the more delicate glans and the urinary meatus to the same trauma with a far more painful result—namely, meatal ulceration. One might as well urge a man to remove his steel helmet in an air raid because it was being dented by falling "flak."

Lister, W. A. (1938). *Lancet*, 1, 1429.

P. A. O'Leary and W. E. Herrell (*Proc. Mayo Clin.*, 1944, 19, 20) record the treatment of a case of late cutaneous syphilis with penicillin. The patient was a 42-year-old married woman who for eight years had had a nodular syphilid of the nose. She was given 20,000 units of penicillin intravenously twice a day for 8 days. The result is described as striking, and three weeks after the course of treatment all that was left was some residual pigmentation. Serum tests for syphilis remained unchanged.

THE LISTER INSTITUTE

Long-term Investigations

The report of the Governing Body of the Lister Institute of Preventive Medicine, given at the recent annual meeting, contains brief accounts of many continuing investigations which cannot be expected to reach finality in any one year. Some of the members of the staff are on active service abroad and seconded to a Government Department. A number of the workers are enjoying research facilities at Oxford, and others at Cambridge. One event of the year was the establishment by the Medical Research Council, which is administering the London blood supply depots on behalf of the Ministry of Health, of a unit at the Institute for research into, and filtration of, blood plasma and serum for transfusion, and the Director of the Institute, Dr. Alan N. Drury, is chairman of the Blood Transfusion Research Committee.

Two of the workers, Dr. R. A. Kekwick and Dr. M. F. Mackay, have been studying problems arising in the large-scale processing of human serum and plasma. They have found that the adjustment of the reaction of plasma to pH 5.4 with sterile citric acid before ether extraction provides a method for the quantitative removal of fibrinogen, as well as for removing the unstable lipid complexes. After readjustment of the product to pH 7 followed by Seitz filtration, a transfusion fluid is obtained which remains stable for at least two or three months. It is added that problems arising in the kaolin processing of plasma have been surmounted and the Serum Unit has been filtering the entire output of the London blood transfusion depots before dispatch to Cambridge for freeze-drying.

Serological and Bacteriological Studies

One of the serological studies undertaken concerns the treatment of louse-borne typhus by anti-proteus OX 19 serum. Dr. A. Felix has been working on this serum from the horse and a few preliminary trials have been carried out in North Africa in collaboration with Capt. T. E. Woodward of the United States Typhus Commission. Six selected severe cases were treated; three patients received the serum intravenously and three intramuscularly. All did well, though one of them had been in a comatose state for several days. These trials have shown that large doses of the serum are well tolerated and that as a result of the injections an initial low-titre OX 19 reaction in the patient's serum can be increased from twenty to thirty times.

Dr. Felix and Miss Callow have continued the typing of typhoid, paratyphoid, and food-poisoning bacilli with the Vi bacteriophage. A paper by them on the typing of paratyphoid B bacilli in this way was published in the *British Medical Journal* of July 31, 1943 (p. 127). One hitherto unknown Vi-phage type of the typhoid bacillus was identified during the past year as being responsible for a small outbreak of typhoid fever. This type does not seem to be indigenous to the British Isles, as it has been traced to a chronic carrier who acquired the infection during the war in South Africa more than forty years ago. On the other hand, a Vi-phage type of *Bacillus paratyphosus* B has been found which must be considered indigenous. The number of known Vi-types and subtypes of the paratyphoid B bacillus is now five.

Nutritional Studies

The Ministry of Food has been anxious to ascertain more accurately the requirement for vitamin A as derived from pre-formed vitamin A and from the provitamin carotene. This has been done by a human experiment carried out on volunteers, who were conscientious objectors, at the Sorby Institute at Sheffield. Since July, 1942, these volunteers have received a diet made as deficient as possible in vitamin A and carotene; a small number have served as positive controls receiving supplements of these substances. Observation was specially directed to the measurement of capacity for dark-adaptation. At the end of a year none of the volunteers showed any definite signs of deterioration of the visual threshold, but after fourteen months one subject began to show this deterioration, with slight skin symptoms, and a very low value for plasma vitamin A, all of which signs progressed rapidly until he was given a small daily dose of the vitamin, when the symptoms slowly regressed. The experiment has indicated how large are the vitamin A reserves in the liver of the healthy human adult.

and that a daily dose of vitamin A, smaller than that usually recognized as the daily requirement, is enough to stop depletion and restore the organism to health, though whether to perfect health is still uncertain.

The nutritive value of the nitrogenous substances of the potato has been under investigation. Weight for weight, the nitrogen of the potato has been found to have a biological value at least equal to that of the proteins of whole wheat, though only about one-half of the potato nitrogen is in the form of protein. It is believed that a supplementary action occurs between the protein and non-protein nitrogenous substances in the tuber, probably attributable to the amino-acids present in the latter, which explains why the total nitrogen of the potato, though half is non-protein, has at least as high a nutritive value for growth as an equivalent amount given in the form of potato protein. The nutritive value of proteins from other foods has been found to be enhanced by the addition of protein-free potato juice.

A nutritional survey of women employed in Oxford factories and of local housewives of similar age and social position was carried out from the autumn of 1942 to the end of 1943. On the whole the nutritional state deteriorated very slightly during that period, but more so among the factory workers than among the housewives.

Other Researches

Work on the cultivation of vaccinia virus on the chorio-allantoic membrane of the developing chick has been resumed with a view to preparing sufficient quantities of suitable virus for field trials and for clinical use in vaccination. The differences in the lesions inflicted on this membrane by strains of virus derived from sheep and those derived from the calf, which were reported four years ago, are being made the subject of further investigation, and it is hoped to determine which strain is the more suitable for Jennerian prophylaxis. Observations are also being made to determine the best method of preserving stocks of cultivated virus and a convenient form in which it can be issued for clinical use.

A large number of studies are recorded on the effects of different combinations of hormones and vitamins on young adult and old rats. Thus vitamin A, B, or C, administered alone, caused only slight changes in the liver and kidneys, but striking changes followed administration of thyroid hormone in non-toxic doses, including pronounced hyperplasia of hepatic cells, hypertrophy of kidney tubules, etc. Simultaneous administration of the vitamins with the hormone did not significantly alter the effect of the latter. Large doses of the hormone produced a pronounced atrophy of cells and other changes, and here vitamin B had a beneficial effect (regenerative hyperplasia of cells).

Many other biochemical, biophysical, and physico-chemical experiments are recorded.

ORDER OF ST. JOHN OF JERUSALEM

The following medical promotions in and appointments to the Venerable Order of the Hospital of St. John of Jerusalem have been announced:

As Knights Capt. H. F. Powell, M.B.E., Lieut.-Gen. Sir Alexander Hood, K.C.B., C.B.E., K.H.P., Lieut.-Gen. Sir Gordon G. Jolly, K.C.I.E., I.M.S., Drs. F. C. Bottomley, O.B.E., and W. Stewart, As Commanders (Brothers), Drs. C. Gardiner-Hill, K. S. Maurice-Smith, F. L. Newton, and C. E. C. Wilson, Brig. W. W. S. Johnston, C.B.E., D.S.O., M.C., Major-Gen. P. S. Mills, C.I.E., I.M.S., Col. H. H. E. Russell, O.B.E., V.D. As Associate Commander (Brother), Dr. A. D. E. Behram, As Officers (Brothers), Drs. H. J. O'D. Burke-Gaffney, O.B.E., H. C. Sinderson, C.M.G., M.V.O., O.B.E., S. J. W. Donald, E. A. H. Russell, O.B.E., V.D., H. E. Skeete, O.B.E., J. S. Harbison, S. F. Chellappa, O.B.E., and N. Caine, Brig. Sir W. S. Duke-Elder, Col. A. H. Harty, C.I.E., I.M.S., and R. Hay, C.I.E., I.M.S., Lieut.-Col. W. George, M.C., T.D., Lieut.-Col. R. F. D. MacGregor, C.I.E., M.C., I.M.S. (ret.), G. Verheese, C.I.E., I.M.S., and J. E. Gray, I.M.S., Capt. T. C. A. Sweetnam and F. W. P. Sullivan, As Associate Officers (Brothers), Lieut.-Col. A. N. Chopra, I.M.S., Major S. A. Paymaster, I.M.S., Capt. G. G. Limaye, Dr. M. N. Mahadevan, As Officer (Sister), Dr. Cornelia B. S. Elwood, C.B.E., As Serving Brothers, Surg. Lieut. Cmdr R. F. Matters, R.A.N., Lieut.-Col. A. I. Cox, I.M.S., Majors J. D. Murdoch, I.M.S., and A. B. Slack, M.C., Drs. J. H. Pettinger, G. A. Fisher, M.C., T.D., C. R. White, R. St. J. Kerm, W. W. King-Brown, G. C. Campbell, L. A. Watson, H. S. Taylor-Young, R. Brown, A. K. MacRae, K. D. Bean, E. M. McAlpine, C. D. Hough, V. F. Ryan, T. J. Coakley, G. R. Lipp, M.C., K. G. Salmon, P. H. Stewart, S. G. Budd, R. McL. Carmichael, J. A. Davies, and C. E. R. Norman, As Associate Serving Brothers, Lieut.-Col. R. M. Kharegar, I.M.S., Capt. B. S. Chalm, Dr. B. Bose, H. N. Dewan, M. F. Bismi, I. Lipedge, S. Bloom, P. R. Kuppuswami and P. Vaidyanathan, As Serving Sisters, Drs. Muriel R. Powell, Daphne W. Dear, Margaret Swete, and Alice M. Headwards.

Correspondence

B.M.R. Determinations on Ambulatory Patients

SIR.—I read with very great interest the paper on the determination of basal metabolism on out-patients by Dr. J. Douglas Robertson (May 6, p. 617). The problem of ambulatory basal metabolic rate determinations arose in the Montreal General Hospital approximately 20 years ago. The method investigated corresponded almost exactly with that of Dr. Robertson, and the conclusions were the same. During the last 20 years we have performed approximately 50,000 basal metabolic rate tests on ambulatory patients, and, as Dr. Robertson has pointed out, "these so-called ambulatory determinations are not significantly different from those tests carried out at the bedside under strictly basal conditions.—I am, etc.,

I. M. RABINOWITCH.

Director, Department of Metabolism, Montreal General Hospital.

Why Tie the Cord?

SIR.—I have read with much interest the letters by Dr. E. W. Price (June 3, p. 772) and Dr. K. J. Franklin (June 24, p. 857) on "Why Tie the Cord?" Whether or not it is necessary to tie the cord depends on the presence or absence of a closing mechanism in its vessels. Certain radiological observations focused our attention on the intra-abdominal portion of the umbilical arteries. For the past year I have been examining sections of these arteries. A full account of the results will be published elsewhere, but the following notes, some of which are based on this work, may be of interest with regard to the present question.

In the intra-abdominal portion of the umbilical arteries sub-endothelial ridges are found which project into the lumen of the vessel. These ridges lie within the internal elastic lamina and the tunica media. They consist mainly of longitudinal and oblique muscle fibres (see Fig. 1). Their prominence

FIG. 1

varies with the state of the vessel. In structure and appearance they resemble the ridges found in the penile and uterine arteries (Kiss, 1921) and the pulmonary artery and ductus arteriosus (Pfeifer, 1902). They are found throughout the intra-abdominal portion of the umbilical artery from approximately the level of the base of the bladder to the umbilicus. It is of some interest to note that Jankovich (1939) described somewhat similar structures in the extra-abdominal portion of the artery. The function of the ridges appears to be to bring about a fairly complete closure of the umbilical arteries following birth—the circular muscle of the tunica media contracting and driving the ridges into the lumen.

With regard to the vein, the muscle fibres in the vessel wall are relatively deficient compared with those in the artery. The circular muscle fibres are found in scattered bundles and do

the parietes by applying powdered asbestos to the surface of the heart and by laying grafts of mediastinal fat against it. His illustrations demonstrate conclusively that vascular channels are formed in such adhesions, both in animals and in man.

Unfortunately the results of this procedure are not encouraging. Feil describes 37 patients treated by the Beck operation: there were 14 operative deaths, and 23 survived. Of the latter, 14 were improved and are still living, 9 died within four months to six years of operation, all from coronary disease, and 5 of these experienced relief of their symptoms. Patients with severe coronary disease rarely survived the operation, and those that did survive were unimproved. Therefore the early case with only slight myocardial damage should be chosen for operation; but even in the later cases of the series, when such selection was being applied, the operative mortality was 35%. Grave as is the prognosis of coronary disease, such a mortality will discourage most physicians from submitting their patients to this hazard. Nevertheless there is now considerable evidence that these operations do, in most cases, reduce the severity of the symptoms and even prolong life if the patient can survive the initial shock. It is therefore to be hoped that future improvements in technique will lower the operative mortality. There is certainly scope for more research in this field.

HEALTH RECORD OF THE U.S. ARMY

The Surgeon-General's statistical report for 1943, circulated by the U.S. Office of War Information, gives some interesting facts and figures. The number of men examined during the year was 5,200,000; the number recruited into the Army was 2,400,000, and into the Navy, Marine Corps, and Coast Guard 900,000; the number rejected was 1,900,000 (36%). The Army certificate-of-disability-for-discharge rates have run rather high. The majority of such discharges occurred within the first three months of service, suggesting that mental and physical defects were missed at the medical recruitment examinations. The health of the U.S. Army has been better than it was at any time during peace. Up to the end of 1943 only 3% of the wounded had died of their wounds. The Army's over-all death rate from disease was 0.6 per thousand per annum, this despite the fact that American soldiers are fighting on all fronts, in all climates, and exposed to all diseases. The death rate for pneumonia before the advent of the sulphonamide drugs was 24%; the present Army rate is 0.7%. The death rate from meningitis, which forty years ago killed 80% of those contracting it, was reduced to 38% in the last war and, through the use of "sulpha" drugs, has now fallen to 4.2%. The admission rate for tuberculosis has declined from 12 per thousand per annum in the last war to 1.2 in the present war. The programme for recruitment of individuals with venereal disease was officially inaugurated in October, 1942. Special V.D. hospitals were built at each of the 34 reception centres, with a total of 6,510 beds. Recruits having venereal disease were referred to these hospitals, where they were examined and treated. The U.S. Army is vaccinated against smallpox, paratyphoid, typhoid, and tetanus. Typhoid fever, which was the scourge of armies until 1912, has been reduced to insignificance. There have been no deaths from typhus, though this disease is endemic in North Africa. There has been no tetanus in the vaccinated, and vaccination against yellow fever has prevented any incidence of this disease. Vaccination is available when there is danger of exposure to cholera and plague. Against the

menace of insects as carriers of disease the sanitary service has developed the Freon pyrethrum bomb which, upon the turning of a spigot, will spray a plane or tent or barrack, killing all flies, mosquitoes, and bed-bugs in the area treated. This spray is non-toxic to man. The synthetic compound known as "DDT" (dichlorodiphenyltrichlorethane) has been introduced for killing lice; the use of this powder (which is also effective against flies) enabled the United States Typhus Commission to prevent the development of an epidemic of typhus fever in Naples. The report on the dental service states that rejections for dental defects ran to around 5%. It was decided then that if a recruit had no malignant disease or extensive osteomyelitis in his jaws he would be accepted regardless of the number of serviceable teeth. This threw an immense load upon the Army Dental Corps. During the years 1942 and 1943 14,600,000 cases were treated, and 31,000,000 teeth were filled; more than 1,400,000 bridges and dentures were supplied, 196,000 dentures mended, and more than 6,000,000 teeth replaced by dentures and bridges.

MEDICAL FILMS

There should be plenty of room for the use of the moving film in medical education. If anyone had doubts on this subject the viewing of the two films recently made by the British Council should have removed them. The moving picture tells a story that often enough can be told with poor effect in words only. In fact there is always the risk that the word will accumulate many meanings remote from what it stands for. One such word is "rehabilitation," which at the moment is in danger of almost becoming a political slogan. The recent British Council film, "Accident Service" (see *B.M.J.*, June 10, p. 789), made it vividly plain to all and sundry just what rehabilitation is. We can think of no better way of informing the medical student of what rehabilitation is than by showing him this film. It is even possible that the film will teach more than a visit to such a centre as Berry Hill Hall, because the film is the product of many minds, and gathers up into one whole all the numerous links in the medical and surgical chain that rehabilitates the injured or diseased person. But films can become an educational force in medicine only if they are well done, and they can be well done only if the expert film technician and the expert medical technician are given a free hand to work out their common problem on an equal footing. The film technique should be as good of its kind as the medical or surgical technique if the student's mind is to be satisfied. Until the perfect library of medical films can be formed we must rely upon the slightly imperfect copies that owe their existence usually to the enthusiasm of amateur medical cinematographers. Full use of the films that now exist can be made only if they are fully catalogued and classified by some central organization. Recently the Scientific Film Association set up a medical standing committee "to further the production and distribution of medical films suitable for circulation within the medical profession, either for training and teaching purposes or for the general dissemination of information." After the war it is hoped to set up a central medical film library, and as a step towards this any doctors who know of or have medical films are asked to inform the secretary of the Medical Standing Committee, Dr. S. J. Reynolds, 14, Hopton Road, Streatham, S.W.16. So that the information about each film may be systematically assembled a questionnaire has been drawn up by the Scientific Film Association which will be sent to any inquirer. Ordinary membership of the Scientific Film Association is open to anyone interested in the subject.

SOME COMMON PAEDIATRIC PROCEDURES A REASSESSMENT FOR CHILD WELFARE PRACTICE*

BY

DOYNE BELL, D.M.

*Physician, Belgrave Hospital for Children; Physician in Charge of
Children's Department, Queen Mary's Hospital for the East End*

It has seemed to me suitable, in addressing this audience, to confine my remarks to such aspects of the subject as are the day-to-day concern of the worker in the child welfare clinic. The choice of a few points of common paediatric procedure for your reconsideration has therefore been based on cases referred to me from welfare centre practice or presented as problems to midwives and students in maternity departments. If, then, my conclusions seem to many to be self-evident, I must plead that to others they have seemed less obvious.

The Crying Baby

Handbooks on the care of babies quite rightly tell their readers that the treatment of the crying baby is to find out the cause of its crying and correct it; yet in practice it is not at all uncommon for mothers to complain that their babies cry for hours on end, and an examination of such babies shows no abnormality to account for this behaviour. Endless and apparently motiveless crying is extremely disturbing to the mother, and may result in such anxiety that lactation fails. Even without such a serious consequence the symptom is distressing both to the baby and to all who hear it, and calls for treatment. I think in many cases, though the crying was started by some momentary discomfort, its persistence is due to the discomfort occasioned by the crying itself. The baby gets hot and its pillow wet, and so the crying continues. In these cases, after excluding by thorough examination an organic cause of pain, the giving of a sedative is amply justified. It is important, however, to give it in sufficient dose to ensure that the habit of crying is broken. Nothing discourages the mother more than to be given a medicine which she hopes will soothe the infant and then to have her hopes frustrated. For an infant 6 months old, for instance, phenobarbitone, gr. 1/2, would be an appropriate dose. The sedative need not be repeated for more than three or four nights as a rule.

Breast-feeding

The commonest errors in the handling of the breast-feeding of the newborn child seem to be due to anxiety and pessimism—anxiety lest the newborn infant should be underfed in the early days of life, and pessimism with regard to the mother's ability to suckle her child. Admittedly the factors influencing lactation are incompletely understood and complex—too complex for detailed discussion here; but it is clear that successful breast-feeding does not depend entirely on mechanical factors such as the stimulation of the nipple by sucking and the emptying of the breast. Endocrine influences of much complexity play an important part, and anxiety or pessimism or a display of even cheerful ignorance by nurse, doctor, or health visitor will often effectively disturb what should be a normal lactation. My plea, therefore, is for a much more intelligent and intensive field study of lactation. Such study would show, among many things, how great is the variation in the appetites of normal newborn babies and in the time taken for lactation to become established. I am depressed at the number of infants discharged from maternity hospitals at the age of 2 weeks or less, wholly artificially fed. Often in such cases I learn that on or about the tenth day after delivery the mother has been given tablets to dry up her milk and told that she has an insufficient supply. There is nothing pathological in the fact that on the tenth day the supply of breast milk is less than 2½ fl. oz. per lb. of the infant's body weight. I think it is a fair generalization to say that, in the case of a healthy mother and infant, it is never possible in the first three weeks to state that lactation will not be established and should be abandoned. I have made it a rule, in a midwifery department where the newborn babies are in my care, that no infant is ever to be given a complementary feed (I except water and saline) without my being notified. As a result such feeding is, in normal cases, practically unknown.

In contrast let me instance a case referred to me last year. A mother aged 20 was sent with her 9-weeks-old infant to see me because he was restless and crying, and vomited. The baby had been born in a private nursing home, and had never been put to the breast. The mother had been purged and had her breasts bound up on the third day, and a variety of proprietary foods had been given to the infant. On examining the mother's breasts I found that a few beads of milk could be expressed. She was obviously disappointed that she had been thought incapable of suckling her child. I gave her the ordinary advice for re-establishing lactation,

but warned her not to be unduly depressed if she failed. She wrote 44 weeks later to tell me that her infant was fully breast-fed. The indiscriminate use of synthetic oestrogens has of course made the re-establishment of wrongly abandoned lactation more difficult.

The study of natural lactation can be carried out only by the paediatrician who sees the baby from birth onwards. The time available to the obstetrician or midwife—two or three weeks as a rule—is too short for a proper study to be made. This, incidentally, is a further argument, if one is still needed, for the paediatric supervision of the newborn babies in maternity units. The premature termination of lactation, like the termination of pregnancy, is a step which may have serious consequences, and should never be undertaken without a full knowledge of the factors involved and a careful consideration of the medical indications.

The formation of an abscess in the lactating breast is a complication of breast-feeding that needs much study. There is apparently a widespread failure to appreciate the aetiological factors and what should be the aim of treatment. Most cases of suppurative in the lactating breast are preceded by obstruction of the milk ducts, producing a tender, knotty breast. Treatment of this condition and prophylaxis of abscess formation should clearly aim at removing the obstruction and re-establishing the milk flow. Taking the baby off the affected breast and tight bandaging are therefore to be condemned.

When an abscess has definitely formed it is still too often forgotten by the surgeon that he has two patients—the mother and the infant. No treatment of breast abscess should be considered entirely satisfactory which does not achieve as its end-result normal lactation. A fissure in the nipple should be considered a danger signal, for it may be a portal of entry for infection to the deeper breast tissues. In any event, the fissure itself is extremely painful and may render breast-feeding from the affected side temporarily impossible. If, on account of pain, breast-feeding has to be suspended, particular care must be taken, while the fissure is under treatment, to prevent milky engorgement of the breast, either by manual expression or by the use of the breast pump. The objects of local treatment of the fissure are disinfection and rest, just as if it were an ulcer anywhere else in the body. There are many ways of achieving these ends, but a very practical method, and one that gives rapid relief of pain, is the application of a lead nipple-shield between feeds.

Artificial Feeding

The technique of artificial feeding should be elastic and be modified to suit the individual infant's requirements, and in this important branch of paediatrics rule-of-thumb methods have little place. One not uncommonly sees infants suffering from dietetic upsets who have been treated by many changes of the brand of dried milk offered but none in the composition or quantity of the food. The only change has been in the branded name on the tin. The slavish belief in the advertised merits of proprietary brands of dried milk has interfered with the wider use of national dried milk. In this respect some hospitals have been much to blame. An infant is admitted to hospital and fed on a proprietary brand of straight full-cream dried milk; if he does well the mother is naturally reluctant to change to national dried milk when the infant returns home. Thus she pays at the chemist's shop three or four times as much as she would pay for the identical product at the food office or clinic.

Respiratory Infections in Childhood

Chronic nasal discharge in small infants with resulting snuffles or nasal obstruction is a very common symptom. The origin of these snuffles is probably a mild catarrhal infection of the nose, but the persistence of the symptom is often due to mistaken attempts to clear the nose with pledgets of cotton-wool. These pledgets are useless for the purpose for which they are intended, and the delicate mucous membrane of the infant's nose is always irritated and often injured by their use, and a chronic infection results. Most cases of snuffles will clear up when the use of such pledgets is discontinued.

Whether tonsils should be removed or not is a question asked frequently in welfare centre practice. It clearly requires careful and individual consideration. No one who has seen some of the bad results of indiscriminate tonsillectomy will fail to realize the importance of a right decision. The tonsil undoubtedly plays a large part in the defence of the respiratory tract of the young child against infection, and its removal while still capable of healthy function will only weaken the defence. I do not think it is an over-simplification of the problem to state that there are but two indications for the removal of the tonsils in children under 5 years old. The first is hypertrophy of the tonsil to a degree which interferes with the child's swallowing; the second is chronic infection of the tonsil, resulting either in repeated auto-infection of the respiratory tract or in the child's becoming a carrier of pathogenic organisms which cannot be eliminated by other means. It is important to remember that a history of repeated acute infections in the child is not necessarily an indication for removal of the tonsils. The repeated infections may be due simply to repeated exposure to an outside source of infection. The same principles

* Lecture (abridged) given in London to the Maternity and Child Welfare Group of the Society of Medical Officers of Health.

should be applied to consideration of the removal of adenoids. The adenoids should be removed if they are the site of chronic infection, or if their hypertrophy obstructs the nasal air-way or interferes with the drainage of the paranasal sinuses or middle ear.

In the prophylaxis of respiratory infection in childhood it is still not uncommon to find that clinics are exposing children to ultra-violet light. The uselessness of this procedure was well shown by Dora Colebrook as long ago as 1929. She studied three groups of children, of which one was exposed to ultra-violet light, another to a screened lamp from which no ultra-violet rays came, and the third served as a control. She found no significant difference in the incidence or duration of respiratory infections in the three groups; the very small and insignificant difference being favourable to the control group. In the absence of any work to contradict these findings it seems to me that the exposure of children to ultra-violet light is quite unwarranted.

Strawberry Naevi

The strawberry naevus or capillary haemangioma is quite a common birthmark, and a great number of cases are still referred to hospital, often with the suggestion that they should be treated with CO₂ snow, with radium, or by excision. The natural history of these naevi was studied by W. A. Lister (1938), and he found, in a series of 77 children with 93 naevi who were watched for periods varying from one to seven years, that there was no exception to the rule that naevi which grew rapidly during the early months of life subsequently retrogressed and, of their own accord, disappeared, on the average at about the fifth year.

My experience is in accordance with Lister's findings. Any form of treatment is bound to leave a scar, whereas natural retrogression of the naevus leaves normal healthy skin. The chief difficulty in practice is to persuade the child's mother that the naevus will retrogress after reaching its maximum size at the age of about 12 months. My practice is to make an exact tracing of the naevus on a piece of "cellophane" or washed x-ray film and transfer this pattern to paper. This paper is dated and given to the mother to keep. She may then observe for herself that the naevus does not further increase in size, but gradually shrinks or fades. In many cases the retrogression starts in patches in the middle of the naevus, but after the age of about 12 months the edges, even if they are the last bits to disappear, do not spread.

Circumcision

This mutilation has a long history which is of great anthropological interest. But its popular justification on hygienic grounds seems to be of quite recent origin and of extremely doubtful validity. As it is not free from hazard and discomfort it is well, when considering it as a surgical procedure, to take stock of the indications for the operation. So far as I know, there is but one—phimosis; this being defined as a stenosis of the preputial orifice which prevents retraction of the prepuce behind the corona of the glans penis. In most cases in which circumcision is performed no attempt is made to assess whether phimosis is present or not; for normally the prepuce of the infant is lightly adherent to the glans, and it is these adhesions which prevent retraction. If the adhesions are divided—and this can easily be done either by digital retraction or with a probe, though I do not suggest that it is a desirable routine procedure—it will be found that phimosis is rare. If the preputial orifice is smaller than the urinary meatus—an extremely rare occurrence—interference with urination will occur and operation is certainly necessary. But I doubt whether operation is indicated in lesser degrees of phimosis in early infancy. Indeed, it has been suggested that some degree of phimosis, as above defined, is normal in the young infant.

I have heard it suggested that a long and inflamed prepuce or the so-called "cauliflower prepuce" indicates circumcision. This condition is in fact an absolute contraindication to circumcision. The "cauliflower prepuce"—the site of cellulitis, oedema, and even ulceration—is the result of an ammonia dermatitis. To remove such a prepuce is to expose the more delicate glans and the urinary meatus to the same trauma with a far more painful result—namely, meatal ulceration. One might as well urge a man to remove his steel helmet in an air raid because it was being dented by falling "flak."

P. A. O'Leary and W. E. Herrell (*Proc. Mayo Clin.*, 1944, 19, 20) record the treatment of a case of late cutaneous syphilis with penicillin. The patient was a 42-year-old married woman who for eight years had had a nodular syphiloderm of the nose. She was given 20,000 units of penicillin intravenously twice a day for 8 days. The result is described as striking, and three weeks after the course of treatment all that was left was some residual pigmentation. Serum tests for syphilis remained unchanged.

THE LISTER INSTITUTE

Long-term Investigations

The report of the Governing Body of the Lister Institute of Preventive Medicine, given at the recent annual meeting, contains brief accounts of many continuing investigations which cannot be expected to reach finality in any one year. Some of the members of the staff are on active service abroad or seconded to a Government Department. A number of the workers are enjoying research facilities at Oxford, and others at Cambridge. One event of the year was the establishment by the Medical Research Council, which is administering the London blood supply depots on behalf of the Ministry of Health, of a unit at the Institute for research into, and filtration of, blood plasma and serum for transfusion, and the Director of the Institute, Dr. Alan N. Drury, is chairman of the Blood Transfusion Research Committee.

Two of the workers, Dr. R. A. Kekwick and Dr. M. E. Mackay, have been studying problems arising in the large-scale processing of human serum and plasma. They have found that the adjustment of the reaction of plasma to pH 5.4 with sterile citric acid before ether extraction provides a method for the quantitative removal of fibrinogen, as well as for removing the unstable lipid complexes. After readjustment of the product to pH 7 followed by Seitz filtration, a transfusion fluid is obtained which remains stable for at least twelve months. It is added that problems arising in the kaolin processing of plasma have been surmounted and the Serum Unit has been filtering the entire output of the London blood transfusion depots before dispatch to Cambridge for freeze-drying.

Serological and Bacteriological Studies

One of the serological studies undertaken concerns the treatment of louse-borne typhus by anti-proteus OX 19 serum. Dr. A. Felix has been working on this serum from the horse, and a few preliminary trials have been carried out in North Africa in collaboration with Capt. T. E. Woodward of the United States Typhus Commission. Six selected severe cases were treated; three patients received the serum intravenously and three intramuscularly. All did well, though one of them had been in a comatose state for several days. These trials have shown that large doses of the serum are well tolerated, and that as a result of the injections an initial low-titre OX 19 reaction in the patient's serum can be increased from twenty to thirty times.

Dr. Felix and Miss Callow have continued the typing of typhoid, paratyphoid, and food-poisoning bacilli with the Vi bacteriophage. A paper by them on the typing of paratyphoid B bacilli in this way was published in the *British Medical Journal* of July 31, 1943 (p. 127). One hitherto unknown Vi-phage type of the typhoid bacillus was identified during the past year as being responsible for a small outbreak of typhoid fever. This type does not seem to be indigenous to the British Isles, as it has been traced to a chronic carrier who acquired the infection during the war in South Africa more than forty years ago. On the other hand, a Vi-phage type of *Bact. paratyphosum* B has been found which must be considered indigenous. The number of known Vi-types and subtypes of the paratyphoid B bacillus is now five.

Nutritional Studies

The Ministry of Food has been anxious to ascertain more accurately the requirement for vitamin A as derived from pre-formed vitamin A and from the provitamin carotene. This has been done by a human experiment carried out on volunteers, who were conscientious objectors, at the Sorby Institute at Sheffield. Since July, 1942, these volunteers have received a diet made as deficient as possible in vitamin A and carotene; a small number have served as positive controls receiving supplements of these substances. Observation was specially directed to the measurement of capacity for dark-adaptation. At the end of a year none of the volunteers showed any definite signs of deterioration of the visual threshold, but after fourteen months one subject began to show this deterioration, with slight skin symptoms, and a very low value for plasma vitamin A, all of which signs progressed rapidly until he was given a small daily dose of the vitamin, when the symptoms slowly regressed. The experiment has indicated how large are the vitamin A reserves in the liver of the healthy human adult.

and that a daily dose of vitamin A, smaller than that usually recognized as the daily requirement, is enough to stop depletion and restore the organism to health, though whether to perfect health is still uncertain.

The nutritive value of the nitrogenous substances of the potato has been under investigation. Weight for weight, the nitrogen of the potato has been found to have a biological value at least equal to that of the proteins of whole wheat, though only about one-half of the potato nitrogen is in the form of protein. It is believed that a supplementary action occurs between the protein and non-protein nitrogenous substances in the tuber, probably attributable to the amino-acids present in the latter, which explains why the total nitrogen of the potato, though half is non-protein, has at least as high a nutritive value for growth as an equivalent amount given in the form of potato protein. The nutritive value of proteins from other foods has been found to be enhanced by the addition of protein-free potato juice.

A nutritional survey of women employed in Oxford factories and of local housewives of similar age and social position was carried out from the autumn of 1942 to the end of 1943. On the whole the nutritional state deteriorated very slightly during that period, but more so among the factory workers than among the housewives.

Other Researches

Work on the cultivation of vaccinia virus on the chorio-allantoic membrane of the developing chick has been resumed with a view to preparing sufficient quantities of suitable virus for field trials and for clinical use in vaccination. The differences in the lesions inflicted on this membrane by strains of virus derived from sheep and those derived from the calf, which were reported four years ago, are being made the subject of further investigation, and it is hoped to determine which strain is the more suitable for Jennerian prophylaxis. Observations are also being made to determine the best method of preserving stocks of cultivated virus and a convenient form in which it can be issued for clinical use.

A large number of studies are recorded on the effects of different combinations of hormones and vitamins on young adult and old rats. Thus vitamin A, B, or C, administered alone, caused only slight changes in the liver and kidneys, but striking changes followed administration of thyroid hormone in non-toxic doses, including pronounced hyperplasia of hepatic cells, hypertrophy of kidney tubules, etc. Simultaneous administration of the vitamins with the hormone did not significantly alter the effect of the latter. Large doses of the hormone produced a pronounced atrophy of cells and other changes, and here vitamin B had a beneficial effect (regenerative hyperplasia of cells).

Many other biochemical, biophysical, and physico-chemical experiments are recorded.

ORDER OF ST. JOHN OF JERUSALEM

The following medical promotions in and appointments to the Venerable Order of the Hospital of St. John of Jerusalem have been announced

As Knights Capt. H. F. Powell MBE, Lieut.-Gen. Sir Alexander Hood, KCB, CBE, KHP, Lieut.-Gen. Sir Gordon G. Jolly, KCIE, IMS, Dr. F. C. Boultonley, OBE, and W. Stewart, As Commanders (Brothers) Drs. C. Gardiner-Hill, K. S. Maurice-Smith, F. L. Newton, and C. E. C. Wilson, Brig. W. W. Johnston, CBE, DSO, MC, Major-Gen. P. S. Mills, CIE, IMS, Col. H. H. E. Russell, OBE, VD, As Associate Commander (Brother) Dr. A. D. E. Behram, As Officers (Brothers) Drs. H. J. O'D. Burke-Gaffney, OBE, H. C. Sanderson, CMG, MVO, OBE, S. J. W. Donald, E. A. H. Russell, OBE, and N. E. Skeete, OBE, J. S. Harrison, S. F. Chellappah, OBE, and N. Caine, Brig. Sir W. S. Duke-Elder, Cols. A. H. Hart, CIE, IMS, and R. Hay, CIE, IMS, Lieut.-Col. W. George, MC, TD, Lieut.-Cols. R. F. D. MacGregor, CIE, VC, IMS (ret.), G. Verghese, CIE, IMS, and J. E. Gray, IMS, Capt. T. C. A. Sweetnam and F. W. P. Sullivan, As Associate Officers (Brothers), Lieut.-Col. N. Chopra, IMS, Major S. As Paymaster IMS, Capt. G. G. Limaye, Dr. M. N. Mahadevan, As Officer (Sister) Dr. Cornelia B. S. Elwood, CBE, As Serving Brothers, Surg. Lieut. Cmdr. R. F. Masters, R.A.N., Lieut.-Col. A. I. Cox, IMS, Major J. D. Murdoch, IMS, and A. B. Slack, MC, Drs. J. H. Pottinger, G. A. Fisher, MC, TD, C. R. White, R. St. J. Kenn, W. W. King Brown, G. C. Campbell, L. A. Watson, R. S. Taylor-Young, R. Brown, A. K. MacRae, K. D. Bear, E. M. Alphonse, C. D. Hough, V. F. Ryan, T. J. Coalley, G. R. Lipp, MC, K. G. Salmon, P. H. Stewart, S. G. Budd, R. M. L. Carmichael, J. A. Davies, and C. E. R. Norman, As Associate Serving Brothers, Lieut.-Col. R. M. Kharegar, IMS, Capt. B. S. Chalmers, Dr. B. Bose, H. N. Dewan, M. F. Bism, J. Lipsedge, S. Bloom, P. R. Kuppaswami, and P. Vaidyanathan, As Serving Sisters, Drs. Muriel R. Powell, Daphne W. Dear, Margaret Swete, and Alice M. Headwards

B.M.R. Determinations on Ambulatory Patients

SIR.—I read with very great interest the paper on the determination of basal metabolism on out-patients by Dr. J. Douglas Robertson (May 6, p. 617). The problem of ambulatory basal metabolic rate determinations arose in the Montreal General Hospital approximately 20 years ago. The method investigated corresponded almost exactly with that of Dr. Robertson, and the conclusions were the same. During the last 20 years we have performed approximately 50,000 basal metabolic rate tests on ambulatory patients, and, as Dr. Robertson has pointed out, "these so-called ambulatory determinations are not significantly different from those tests carried out at the bedside under strictly basal conditions.—I am, etc.,

I. M. RABINOWITCH.

Director, Department of Metabolism, Montreal General Hospital

Why Tie the Cord?

SIR.—I have read with much interest the letters by Dr. E. W. Price (June 3, p. 772) and Dr. K. J. Franklin (June 24, p. 857) on "Why Tie the Cord?" Whether or not it is necessary to tie the cord depends on the presence or absence of a closing mechanism in its vessels. Certain radiological observations focused our attention on the intra-abdominal portion of the umbilical arteries. For the past year I have been examining sections of these arteries. A full account of the results will be published elsewhere, but the following notes, some of which are based on this work, may be of interest with regard to the present question.

In the intra-abdominal portion of the umbilical arteries sub-endothelial ridges are found which project into the lumen of the vessel. These ridges lie within the internal elastic lamina and the tunica media. They consist mainly of longitudinal and oblique muscle fibres (see Fig. 1). Their prominence

Fig. 1

varies with the state of the vessel. In structure and appearance they resemble the ridges found in the penile and uterine arteries (Kiss, 1921) and the pulmonary artery and ductus arteriosus (Pfeifer, 1902). They are found throughout the intra-abdominal portion of the umbilical artery from approximately the level of the base of the bladder to the umbilicus. It is of some interest to note that Jankovich (1939) described somewhat similar structures in the extra-abdominal portion of the artery. The function of the ridges appears to be to bring about a fairly complete closure of the umbilical arteries following birth—the circular muscle of the tunica media contracting and driving the ridges into the lumen.

With regard to the vein, the muscle fibres in the vessel wall are relatively deficient compared with those in the artery. The circular muscle fibres are found in scattered bundles and do

not form a complete ring. Although there are ridges projecting into the lumen they are poorly developed and deficient in muscle fibres (see Fig. 2). Connective tissue is much in evidence.

FIG. 2

The closing mechanism—namely, circular muscle and longitudinal ridges—is thus poorly developed in the umbilical vein. It should be noted, however, that Barclay, Franklin, and Prichard (1942), as a result of investigating the ductus venosus by means of radio-opaque substances, have demonstrated in certain animals a closing mechanism in the duct at its commencement.

There is no doubt, therefore, about the existence of a closing mechanism in the umbilical vessels, and although that in the vein does not appear very marked the mechanism in the ductus venosus may make up for this deficiency. In the African natives described by Dr. Price this closing mechanism in the umbilical vessels seems to function satisfactorily, but this is not always so. In this country, bleeding from an umbilical stump, even after it has been ligated, is not uncommon, and occurs at least often enough to warrant the suggestion in some textbooks that a second ligature should be applied to the umbilical-cord stump. Even in Rachmanow's cases, quoted by Dr. Franklin, although he found the cord did not need to be tied in 83% of his 10,000 patients, it had to be ligated in the remaining 17%—and that is not exactly a small number. One could perhaps account for Dr. Price's findings by racial difference. All one can say is that in the umbilical vessels a closing mechanism does exist, but this mechanism cannot always be depended upon. It would seem advisable, therefore, to continue ligating the umbilical-cord stump.—I am, etc.,

Department of Anatomy, University of Glasgow.

Perineal Tears in Normal Confinements

SIR,—I have been medical officer to an emergency maternity hospital since September, 1940, and I have been able to note the number of perineal tears which occur and which require one or more stitches. This hospital deals only with normal confinements, and the figures given below are for cases attended by midwives only; forceps cases are not included. I have personally dealt with all tears.

In the first 1,000 cases there were 236 tears: primiparae 191, multiparae 45; approximately 23.5%. I was surprised at this figure, as in private work the number of cases in which a doctor is called in seems very small. Through the kindness of Dr. A. E. Tibbitts, medical officer of health for Notts, I have obtained the percentage of medical aid notices sent in by midwives in 1,000 cases. The figure is 11.3%, and this includes all cases which require assistance—i.e., malpresentation, obstructed labour, etc.—and not only for perineal tears.

The only conclusion one can come to from these figures is that there are a considerable number of cases with perineal tears in domiciliary maternity work which are left without attention.—I am, etc.,

Retford.

H. E. HUMPHRYS.

Infant Feeding

SIR,—In my work as a public vaccinator I have been impressed by the frequency with which I have come across mothers who complain of the fretfulness, tendency to prolonged crying, and failure to settle after feeds of their infants. My first inquiry in these cases almost always obtains the same answer. What quantity of milk is given at each feed? With breast-fed babies the reply is usually "Twenty minutes"; if the bottle is used it is "six ounces" or "seven," etc., as the case may be. In other words, the mothers have had it impressed upon them that baby should be given a fixed amount based on its age.

There are two reasons why this impression is made on mothers in clinics by nurses and health visitors, and even a paediatrician who wrote in your columns recently: (1) No allowance is made for the fact that a baby's appetite may vary, and vary it certainly does. (2) The boggy of overfeeding. Now it follows that if we are to make allowance for the fact that a baby's appetite varies we can only do so by giving the baby as much as it wants at each feed, and the invariably excellent results of so doing are sufficient proof that this practice is based on sound common sense.

Provided the quality of the milk is correct, the natural act of regurgitation in a greedy baby makes overfeeding impossible, and another cause of any symptoms such a baby may have should be sought. I believe that a very great advance in infant feeding, to say nothing of preventive medicine, would be achieved if all concerned would base their advice to mothers on these fundamental common-sense facts, and if the manufacturers of milk powders could be persuaded to remove from their tins, etc., the columns of figures linking the age of the child with fixed volumes of milk, leaving only details of the proportion of powder to water to ensure the correct mixture.—I am, etc.,

Winfrith, Dorset.

P. R. BOUCHER.

Milk for School-children

SIR,—In your annotation on nutrition and the war (July 15, p. 84) you state, apparently on the authority of Dr. V. P. Sydenstricker, that "growing school-children, however, do not get enough first-class protein—youngsters of 6 get only half a pint of milk daily." The first contention may or may not be true, but a child of 6 can get half a pint of milk daily on his household ration and, in addition, one-third or two-thirds of a pint of milk at a reduced price under the Milk-in-schools Scheme, of which 76.4% of elementary-school children avail themselves.—I am, etc.,

Board of Education, S.W.1.

J. ALISON GLOVER.

Estimation of Dental Caries

SIR,—Dr. Dorothy Smith implies (July 15, p. 94) that because Lady Mellanby has shown that caries detectable by probe and mirror alone has decreased since 1929 the investigation should not have been undertaken. Such criticism is as ungenerous as it is invalid.

The Dental Board, with an income of £20,000, devotes £250 to dental research. The official journal has not even commented on a paper of far-reaching significance to the dental profession.

Criticism from Oxford of the methods of a distinguished layman in the field of dietetics and dental research is singularly misplaced.—I am, etc.,

Blackheath.

GUY NEELY.

Stomatology

SIR,—Much is being written about the practice of medicine and the training of the medical student, but nothing so far has been said about that increasingly important branch of medicine which, if I may use the term better known on the Continent than here, comes under the heading of stomatology.

n Continental usage this term designates the study of the abnormalities and diseases of the mouth, including the teeth, as a positive branch of medicine and not as a subspecialty of dentistry.

I hope that the respective findings of the Goodenough and the Teviot Committees will be so co-ordinated ultimately as to incorporate stomatology as a recognized study within the acuity of medicine.

Machinery for producing many more practitioners in this branch is especially necessary at the present juncture when there is a move to simplify the dental training and, in some quarters, a strong desire to separate dentistry from medicine.

From stomatologists should be drawn the appropriate consultants in a fully organized social health service, and it would be to them that the public might justifiably look for productive research in the biological complexities of the prevention of dental diseases.—I am, etc.,

London W 1

C BOWDLER HENRY

Pentothal Anaesthesia

SIR—The correspondence in your columns on the administration of pentothal, started by Dr Montuschi (May 27, p 731) and followed by letters from Dr Sandiford and myself (June 17, p 825), was originally intended to help many relatively inexperienced anaesthetists, in the Forces and on the Home Front, in the use of this drug. In your issue of July 15 (p 93) you publish two letters—one from Mr Thacker Neville and the other from Dr Oswald Murphy. The only point that these two letters have in common is that they both apparently stray from this original intention. Mr Thacker Neville's letter I consider to be most dangerous for the following reasons.

1 Operations on the nose and throat, in which there is a possibility of blood, pus, mucus, or other debris in the pharynx, are very likely to be complicated by laryngeal spasm, and the inexperienced anaesthetist should, except for induction, avoid pentothal, which is especially liable to this complication. Mr Neville makes no mention of any packing, posture, or suction. Some or all of these are essential to prevent aspiration of debris or initiation of laryngeal spasm.

2 He considers picrotoxin to be "far superior to oxygen." Picrotoxin is a very potent convulsant, and it is only indicated in gross overdose of barbiturate. I have never had to use it during anaesthesia, although I always have it handy and have used it successfully in cases of attempted suicide by barbiturates. Maintenance of a clear airway, careful dosage, and the liberal use of oxygen by controlled respiration where necessary, should avoid the need for picrotoxin.

3 Mr Neville's fourth precept—never to give as much as morphine gr 1/4—is not in accord with his self-confessed practice. A few days ago he did a septum, Caldwell-Luc, phenoidectomy and tonsillectomy all on the same patient, who had received morphine gr 1/4 as part of his premedication.

4 I can conceive of no pathological reason why painting the face with industrial spirit should cause the death of a woman inadequately anaesthetized with pentothal. Such unsubstantiated bogies cause an air of witchcraft and voodoo to attend the administration of anaesthetics, which should be a rational procedure. Such bogies, once started, are very difficult to track down. Here is one at its source and it should be promptly exorcized.

5 Nowhere in his letter does Mr Neville mention any scheme of dosage, so his extra notes do not add anything to Dr Sandiford's most helpful advice.

Dr Murphy, on the other hand, errs on the side of extreme caution. Much of his advice is a counsel of perfection, which we are unable to attain under war conditions.

1 There are not enough experienced anaesthetists available to restrict the use of this valuable drug to them alone. But they can by helpful advice and sound example, save many a patient his life and many an occasional anaesthetist the unpleasantness of discovering the snags for himself.

2 Pentothal, in suitably small doses is excellent for shocked, toxic or debilitated cases, but the anaesthetist must know how to ascertain the correct dose, and in such cases the inexperienced should use the anaesthetic agent he knows best.

3 I agree that the strength of pentothal solution should never exceed 5%, and should be weaker for more serious cases.

4 An assistant, if available is useful to hold up the jaw, but this act does not necessarily preclude the possibility of laryngeal spasm.

5 Isn't Dr Murphy's rate of injection rather too slow? At this rate he must have been injecting for 20 minutes to induce anaesthesia in the second case he quotes. Pentothal is excreted so rapidly in the resistant patient that if injection is very slow the patient is excreting it as fast as it is injected.

Finally, I would suggest that pentothal anaesthesia is not only "not always child's play," it is never child's play. I tell my students that there is no such thing as "fool proof" anaesthesia, but fools should not attempt to give anaesthetics.—I am, etc.,

London W 1

F W ROBERTS

Sodium Pentothal in Nasal Operations

SIR—While reading Mr Thacker Neville's account of his only death under pentothal anaesthesia (July 15, p 93) I was arrested by the statement of his anaesthetist that death was due to the application of industrial spirit to the face (hardly a severe surgical stimulus) during the induction of anaesthesia. In the absence of any mention of the occurrence of laryngospasm, rightly or wrongly I gained the impression that death was considered to be due to primary cardiac failure. I should welcome the opinion of other anaesthetists as to the possibility of such an occurrence. In my opinion, when using pentothal in nasal surgery, the most important safety factor is efficient post-nasal packing to prevent any blood reaching the larynx and setting up laryngospasm. I should also like to stress the futility of anything except the gentlest artificial respiration in severe cases of laryngospasm until the cords relax, when the administration of oxygen under pressure is life-saving. Finally, in cases of cessation of respiration due to pentothal overdose, relative or absolute, while not denying the beneficial effects of intravenous picrotoxin, I should, after the adoption of the Trendelenburg position, place rhythmical inflation of the lungs with oxygen under pressure as the most certain therapeutic measure, and would go so far as to say, "Never use pentothal unless there is at hand some means of carrying this out"—I am, etc.,

E R DINGLE

Hon Anaesthetist, Darlington Memorial Hospital

The Cold Agglutinins

SIR—I have read with interest the paper by Dr Currie and your leading article on cold agglutinins (July 1, p 16). These agglutinins may be either specific or non-specific. Auto-agglutinins usually belong to the latter class, and those which are active at greater than room temperature have been found in association with many morbid conditions, but rarely occur in the blood of healthy persons.

One of the most important features of autohaemagglutination is the "critical temperature" at which the antibody fails to react with the patient's cells. I have seen auto-agglutinins associated with haemolytic anaemia on three occasions and in all these cases the critical temperature was greater than 30°C. The many other instances of autohaemagglutination which I have studied have not shown a critical temperature as great as 30°C, nor has any case been one of haemolytic anaemia. I therefore attach considerable importance to this feature, which seems to be of more significance than, for example, the antibody titre.—I am, etc.,

Intravenous Barbiturates in Hysteria

SIR—Psychiatrists will read with some interest the article by Drs Lambert and Linford Rees (July 15, p 70) on the treatment of 247 cases of hysteria by three separate methods—intravenous barbiturate, general psychiatric treatment, and hypnosis. The interest, I think, will not reside so much in the fact which emerged that there were no significant differences in the results of the three forms of treatment. The more important, not to say startling, fact is that mere symptomatic recovery is accepted by the authors as the adequate test for evaluating the results. "The criterion of return to duty as an indication of therapeutic success was found to be unsatis-

factory" mainly, apparently, because it implied the need for a total assessment of the case and not merely improvement in the symptoms.

With an easy therapeutic target of this kind, spectacular successes are to be expected. In fact, from my experience, I would say it is pretty certain that equally good results would be obtained in a similar group of cases if they were given no special treatment, but simply told that they would not be sent back to duty if they recovered from their symptoms within a specified time.

We evidently had higher therapeutic aims in the last war, and I suggest that the article would have been somewhat less misleading if the authors had referred not to the treatment of hysteria, as they do, but to the treatment of the symptoms of hysteria.—I am, etc.,

London, W.1.

FREDERICK DILLON.

Chemotherapy in Otitis Media

SIR,—I read with great interest the article by Mr. Dingley on the dangers of sulphonamide therapy in otitis media (June 3, p. 747) and with astonishment some of the correspondence which has followed. I am quite sure that neither by word nor by suggestion did Mr. Dingley propose the abolition of sulphonamides in all types of middle-ear infection, but what he was emphasizing was that chemotherapy was not, in itself, a substitute for myringotomy in a case where pus was present behind the drum. With this contention I find myself in hearty agreement. That sulphonamide therapy in early cases of otitis media will hasten their cure and thereby reduce the number that would doubtless have gone on to a mastoid infection will, I think, be a matter for general acceptance. The response is often dramatic; but I do feel that when pus is present behind a drum, that drum is safer and better opened, and there is more chance thereby of avoiding the mastoid operation than by pouring in sulphonamides, even in full doses.

I agree, too, with Mr. Dingley in his warning that the sulphonamides in such cases can mask symptoms. I have seen several, and the lesson to be learnt is, I think, that while sulphonamides do achieve great things it is not reasonable to expect them to do everything, least of all finally to sterilize and render innocuous pus that is behind the ear-drum.—I am, etc.,

Cheam, Surrey.

C. CARRON BROWN.

Mastoiditis and Mastoidectomy

SIR,—I have carefully and with deep interest read Mr. W. H. B. Magauran's letter (July 1, p. 23) in answer to mine of March 18 and May 6. He states that he has performed during recent months 97 conservative mastoid operations. Conservative! I cannot conceive of any less conservative method of treating an ear case than by mastoidectomy. If this is Mr. Magauran's idea of the meaning of conservative, then he and I are poles apart, and I cannot accept his definition of the words dangerous, disfigurement, pain, and good or bad results.

Mr. Magauran will agree that the majority of the cases he operates upon are those typical ones described in every textbook as cases of otitis media which require the operation of mastoidectomy. This, I again state, I have through years of observation and as the result of my experience since 1912, and more especially since 1919, come to disagree with entirely, and to form the opinion that the teaching for the last forty years or so on this subject has been wrong and disastrous to the public.

The 14 cases which Mr. Magauran cites are remarkably like those I quoted as following mastoidectomy: (1) *General streptococcal meningitis*.—I find that has been the most frequent cause of death after mastoidectomy. (2) *Meningeal reactions with turbid C.S.F.*—Cause similar but much less reaction. (3) *Otitic hydrocephalus and subdural abscess*.—Caused by chiselling in a septic cavity and removing the bony barrier separating it from the brain. The other cases—lateral sinus infection (he missed out infection of the jugular vein), external rectus paresis, facial paresis, vertigo, extradural abscess, etc.—have all been seen by practitioners to have followed mastoidectomy. Bezold's abscesses have been opened frequently

and the bone at the tip of the mastoid found cupped from the outside but hard and sound when the aural surgeon has gone on to open the mastoid bone, proving that the infection comes from outside and has not penetrated through this very hard bone. As to painful dressings, the patient is the one to answer that; the distress is not easily forgotten.

I am glad Mr. Magauran agrees that those cases which he calls "mastoiditis" and I call "otitis media" can be cured conservatively. He states: "In a series of 132 cases of acute mastoiditis treated in one hospital complete resolution occurred in 77 cases with conservative treatment. . . . The remaining 55 cases had mastoid operation either immediately or after conservative treatment had failed." Mr. Magauran thus differs from his fellow aural surgeon, Mr. Gordon Mowat, who, in the *Journal* of April 8 (p. 512), in answer to my letter of March 18, writes: "Almost any case of mastoiditis will subside without operative treatment, but, nevertheless, infection of the mastoid is present, and the ears continue to discharge." Mr. Mowat states his belief that all cases of discharging ears should have mastoidectomy performed within six weeks of the discharge commencing. He does not say how soon he would operate, whether immediately or on the last day of the six weeks. Nevertheless he states that mastoiditis is never cured except by mastoidectomy. I, on the other hand, find that all those cases can be cured by a very simple conservative treatment. I maintain that if those of the 55 cases cited by Mr. Magauran as having had the mastoid operation performed immediately had been given a chance of conservative treatment, and those which were operated upon after a period of conservative treatment had been treated as I have advised, the whole 132 cases would have completely recovered—not just 77.

Mr. Magauran and his fellow aural surgeons would earn the undying gratitude of a multitude of sufferers if they would agree to try proper and careful conservative treatment, say, for the next six months. The tools required are few—a small bottle of hydrogen peroxide, a small bottle of methylated spirit, some cotton-wool, and a pair of fine aural forceps. The other requisites—one of the emollient types of drops ("sedonan"), aspirin and phenacetin powders, an inhalant—are not so immediately necessary. The time taken is not long. I spend about half an hour on my first visit and ten minutes or a quarter of an hour on my subsequent ones. I visit for about three days running and then once a week. My average time for a cure is six weeks—i.e., about nine visits. Some cases clear up remarkably quickly, and often those with the most alarming symptoms of pain, pushing forward of the ear, etc. Others have a fairly harmless watery discharge for many weeks, but know how to treat themselves, and only call to see me once in a while to be reassured that all is going well. The pain I practically stop on my first visit. In fact I do not leave the house until the patient smiles and says there is little or no pain, and in small children generally when they have fallen asleep after relief from pain.

Mr. Magauran's misgiving is very natural; it is a good sign. It was my misgiving, after carefully watching aural surgeons operate and seeing young and healthy friends and relatives die or have a great struggle to recover from mastoidectomy that made me refuse ever to have a patient of this large practice operated upon for "mastoid," and the results, as I state, have been uniformly excellent. Treatment with such results for 25 years is surely worth a real trial. Courage, patience, and care are all that is required. The first is very necessary after we have all been taught just the reverse of what I have stated. I advise doctors, if they do have to have a patient operated upon for otitis media, to go to the theatre and see the crude, unscientific operation it is, and ask themselves seriously, Is this operation necessary and is it a safe one?—I am, etc.,

Edinburgh.

H. HILTON BROWN.

Sulphonamide Prophylaxis of Gonorrhoea

SIR,—It was most surprising to read (May 20, p. 695) that responsible authorities had used sulphonamides in the prophylaxis of gonorrhoea. Here in the Gold Coast there has never been any effective control of the sale of these drugs to the public. As everybody gets gonorrhoea they soon became very popular, and for years now the people have been

dosing themselves with tablets indiscriminately, not only for gonorrhoea but for every kind of complaint, even using them as a "pick-me-up."

In times of scarcity the price has risen to a shilling a tablet; forged tablets have appeared on the market; and professional thieves have found stocks of sulphonamides more attractive than tills. Thus conditions have been ideal for the development and spread of resistant strains. Already in the larger centres a high proportion of gonococcal and puerperal infections fail to react to a sulphonamide; it may very soon become quite useless.

Thus to throw a valuable drug to the wolves of commerce seems an inexcusable insult to medical science. Will penicillin share the same fate?—I am, etc.,

Kotondua, Gold Coast.

G. I. ALEXANDER.

Gonorrhoea in North Africa

SIR.—The cases described by Col. Campbell are typical of those we used so frequently to come across in the days of irrigation treatment. As I pointed out some ten years ago the sequelae of post-urethral and epididymal troubles are probably due to irrigation with lodgment of the infection in the seminal vesicles. When this occurs vasotomy—as I then advocated—is the only treatment which will bring about a cure. This also holds good to-day for all cases in which sulphonamide treatment fails. If Col. Campbell will treat his cases by vasotomy he will find that they will not require to remain in hospital for more than three to four days, by which time all discharge and symptoms will have disappeared and the patient be fit for duty.—I am, etc.,

Sandbach, Cheshire.

J. F. PLART.

Stilboestrol in Cancer

SIR.—On my return from a holiday I was interested to read your annotation (July 1, p. 17) wherein you stated that Huggins of Chicago was the first to suggest that stilboestrol might play an important part in the treatment of malignant disease, and that you considered the evidence is strong that its mode of action is by inhibiting the gonadotrophic hormone of the anterior pituitary.

I am unfortunately not in a position here to find out when Huggins thought of it, but may I with all due humility point out that I, quite unaware of Huggins's work, also suggested this treatment in a letter to the *Journal* of July 27, 1940 (p. 133), mentioning that stilboestrol most probably had an inhibitory effect on the secretion of the anterior pituitary, and quoting S. L. Noble's experiments in support of this theory. Do please read it with some imagination in Britain as well as the Americans.

The use of stilboestrol in cancer is full of promise, and I am pleased to know that the clinical experiments are to be continued.—I am, etc.,

Lophland, Wigan

J. THOMSON SHIRKAW.

Tarso-metatarsal Dislocation

SIR. It was with great interest that I read Surg. Lieut. Dorrell's account of a case of tarso-metatarsal dislocation in our issue of July 1.

I have in course of preparation an article describing five cases of this dislocation which it has fallen to my lot to treat during the last 2 or 3 years. In three of these the injury has been almost identical with that described by Mr. Dorrell—two the foot was crushed by the landing-wheel of an aircraft and in the third by the wheel of a double-decker bus. In each case the vehicle was moving very slowly (the aircraft ere being towed into a hangar and the bus was reversing), and I agree that it is the slow crushing of the foot which reduces the dislocation. My treatment was similar to Mr. Dorrell's, but the bus injury required skeletal screw action with wires through the calcaneus and metatarsal heads. In the other cases reduced easily by manipulation with a instant chick.

As Mr. Dorrell points out, the immediate prognosis is good at late prognosis is problematical. I have been unable to follow up my cases for longer than 6 months.—I am, etc.,

Ulverston

DAVID A. RICHMOND,
Surgeon, F.M.S.

Obituary

SIR HUGH RIGBY, BL., K.C.V.O., F.R.C.S.

We regret to announce the death on July 17 of Sir Hugh Rigby, Sergeant-Surgeon to the King from 1928 to 1932, and consulting surgeon to the London Hospital and the Poplar Hospital for Accidents. In 1922 he operated on the late Duke of Kent, then Prince George, for appendicitis; and it was he who on Dec. 12, 1928, performed at Buckingham Palace the operation for empyema which was the turning-point in King George V's very severe and protracted illness.

Hugh Mathison Rigby was born in Dublin on May 19, 1870, son of John Rigby, M.A., late superintendent of the Royal Small Arms Factory at Enfield. He was educated at Dulwich College and at University

Ullott and Fry

College, London, and studied medicine at the London Hospital, where he soon made his mark as a man of great promise. He graduated M.B. Lond. in 1895, B.S. (with first-class honours and gold medal) in 1897, and M.S. in 1901; and obtained the F.R.C.S. Eng. diploma in 1900. At the London Hospital he held a succession of junior posts: house-surgeon and house-physician immediately after qualifying, and then surgical registrar, demonstrator of anatomy and tutor in elementary clinical surgery, and demonstrator of clinical pathology. He was elected assistant surgeon to the hospital in 1902 and later became full surgeon. During the last war he served, with the rank of colonel, A.M.S., as consulting surgeon to the B.E.F. in France and to the London District. His services were mentioned in despatches and he was created K.C.V.O. in 1918.

Sir Hugh Rigby was appointed surgeon-in-ordinary to the Prince of Wales and surgeon to the Prince of Wales's Household in 1923, and Sergeant-Surgeon to the King in 1928. He was created a baronet in June, 1929, and became Honorary Surgeon to the King in 1932. He retired from the active staff of the London Hospital before reaching the age limit and was elected consulting surgeon, but he continued in private practice for some years. In addition to his duties at the London and the Poplar Hospitals he has been surgical consultant to the City of London Maternity Hospital, to the East Ham Hospital, and to a number of cottage hospitals in the neighbourhood of London. In 1931 he received the Honorary Fellowship of the Royal College of Surgeons in Ireland, and two years later the honorary degree of M.Ch. from the National University of Ireland.

When he finally gave up active work Sir Hugh Rigby went to live at his country home, Long Dufford, Petersfield, Hants. Throughout his career he was essentially a working surgeon, sound in judgment and in action, inspiring the confidence of all who served him and all whom he served. He avoided publicity and left medical politics to others. His writings were few: an occasional paper on a surgical subject and the article on diseases of the oesophagus in *Choyce's System of Surgery*.

SIR WILLIAM LISTER

We have received the following appreciation from H. B. S.:

As one of the younger generation of eye surgeons I wish to pay a tribute to Sir William Lister, whose example as an eye surgeon was quite admirable. Those of us who attended his clinic and his operations at Moorfields will always remember him for his humanity and kindness in handling patients, his intense enthusiasm for ophthalmology, and his exquisite skill as an operator. In the theatre his behaviour gave us a perfect example of the qualities that make a great surgeon: imperturbability, a high degree of technical skill

which never varied whatever the circumstances, and a quiet orderly manner which gave confidence to the patient and the theatre team. His grace and his unhurried ways were good to see. His few courteous words to a patient on entering the theatre to undergo the ordeal of an eye operation under local anaesthesia never failed to give reassurance, and when the operation was over and the dressings applied a gentle tap on the shoulder and a quiet voice saying, "All has gone very well and you have behaved admirably," did much to induce that state of contented composure so necessary after an eye operation.

As a teacher he was gifted with dramatic talent in describing a case. So vivid were these accounts of his clinical experiences that their memory is quite indelible. Some of us, now 15 years or more after he taught us, can recall fully the contusion in the eye of the Charterhouse boy keeping wicket and the complications which befell the fine cavalry officer suffering from basal-celled carcinoma of an eyelid, and others.

He belonged to a generation of great men in the field of ophthalmology. For those of us who have had the privilege of being taught by him his memory will remain ever fresh in our minds as a most courteous and gallant gentleman, a surgeon of the highest quality, and a teacher whose enthusiasm has given us a lasting inspiration.

Dr. ROGER NELSON WILCOX, medical officer of the East African Medical Service, died on April 10 at Salisbury Hospital, Southern Rhodesia, after an illness of two months. Born in 1903, the younger son of George Wilcox of Ealing, London, he was educated at St. Paul's School and received his medical education at St. Thomas's Hospital, qualifying M.B., B.S. Lond. in 1929, and obtaining the D.L.O. in 1930. After holding the posts of house-surgeon to the ear, nose, and throat department at St. Thomas's he then became house-surgeon at the Kent and Canterbury Hospital. Joining the Colonial Medical Service after a course at the Tropical School, where he obtained his D.T.M.&H., he was posted to Nyasaland in 1931, where he served for 13 years and continued there until his death. He was a very keen member of the B.M.A., and attended all meetings of the Nyasaland Branch, whose president writes: In harness until his last illness, Wilcox's premature death is deeply mourned by his many hundreds of friends in Nyasaland. He was beloved by all his patients, who were quick to realize that his shy manner on first acquaintance was merely superficial. As well as his great service to the Europeans in Nyasaland as medical officer in charge of Blantyre European Hospital he also worked for many years for the African community, and he was stationed at Port Herald, Karonga, and Kota-Kota Districts. He is deeply missed by his African staff and by all his Indian and African patients. He was a very able surgeon and specialized on the ear, nose, and throat. In particular, his old friends in Blantyre and his colleagues in Nyasaland and the district officers with whom he was stationed feel his passing has left a great gap. He was an excellent diagnostician and very kind-hearted with all with whom he came in contact. He was a wonderful listener and had a very keen sense of humour, and was a staunch and loyal friend. He was also a keen sportsman, playing an excellent game of tennis and golf.

News has reached England of the death of ROSS MILLAR, M.A., M.D., C.M., at Ottawa on June 15. Dr. Millar will be remembered by many of the medical officers of the R.A.M.C. in the Third Army during the 1914-18 war, where he served for two years with No. 37 C.C.S., and for the final year of the war with No. 9 C.C.S. as surgical specialist. After the close of the war Dr. Millar returned to his home in Nova Scotia, where he resumed his private surgical practice and was elected a Fellow of the Canadian College of Surgeons. In 1928 he was appointed Director of Medical Services in the Dominion Department of Pensions; and he moved to Ottawa, where he resided until his death. He joined the Halifax Branch of the B.M.A. in 1906 and remained an enthusiastic member of the Association after its Canadian local units were disbanded.

Dr. FRANCIS WHITE HOPE ROBSON, who died on July 2 at Bournemouth, received his medical education at Edinburgh University and the Royal College of Surgeons, Edinburgh. He graduated M.B., C.M. in 1893, and in 1900 took the M.D. with honours; he also held the Medico-Psychological Certificate. After a few years in house-surgeon appointments and four years in a country practice he settled in Southampton and had a busy practice there for 32 years. He held an appointment as public vaccinator for the Shirley district, and also acted as test lymph vaccinator in Southampton for the Ministry of Health. He was for 15 years medical officer to the Southampton Corporation children's homes. He took an active part in Southampton medical work; and was secretary to the Panel Committee for five years after the National Health Insurance Act came into force;

he was also on the committee and acted as treasurer to the local public medical service when Southampton played a leading part, and was among the first to enter the fight in what was known at that time as the Battle of the Clubs. He also was a member of the Southampton Insurance Committee, Tuberculosis Committee, and the Medical Service Subcommittee. Hope Robson retired to Bournemouth in 1936. He was a member of the B.M.A. for over 40 years. He invented a simple aspirator which could be operated with any ordinary syringe, and so eliminated the need for using a suction pump.

Dr. FREDERICK HENRY died at his home in Oldpark Road, Belfast, on July 5, aged 43. He was the second son of the late Major Robert Henry of the Indian Army, and qualified M.B., B.Ch., B.A.O. of the Queen's University of Belfast in 1927. After some experience in general practice in Liverpool and in Glamorganshire he returned to Belfast and gained for himself a growing practice and the confidence and affection of his patients and his colleagues. He dearly loved his work and left nothing undone to elucidate a problem or to relieve suffering.

"C. G. L." writes: A host of doctors will learn with sorrow of the death of Mr. A. HARDES, who for 30 years was with what is now the British Medical Bureau, where he managed the "locumtenens department." Here he was the intermediary between thousands of "tenentes" and the territorial owners of "loci," and to his task he brought gifts of kindness; helpfulness, insight, and tact. To many he was but a voice over the telephone, but his personality came over the wire in the same way as the impact of an actor's personality may come over the wireless.

The Services

Capt. E. J. Bowmer, D. H. McCollum, and F. Zangen, R.A.M.C., and Capt. T. Stephens and Lieut. T. G. Jones, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Italy.

CASUALTIES IN THE MEDICAL SERVICES

Killed.—War Subs. Capt. J. D. Laurie, R.A.M.C.

Died.—Major R. J. Franklin, R.A.M.C.

DEATHS IN THE SERVICES

By the death on July 15 at Birnam of Col. FREDERICK PERCIVAL MACKIE, C.S.I., O.B.E., M.Sc., M.D., F.R.C.P., F.R.C.S., I.M.S., that service has lost one of its most distinguished members at the age of 69. He was educated at Dean Close School, Cheltenham, at the Bristol Medical School and St. Bartholomew's Hospital, and qualified in 1897. In 1902 he passed the F.R.C.S. Eng. and in the same year gained first place in the entrance examination for the I.M.S. and won prizes at Netley. In 1903 he was medical officer to the Younghusband mission to Tibet and in 1905 entered the Bacteriological Research Department as assistant director of the Plague Research Laboratory, Bombay. Among other important research appointments he was a member of the Uganda Sleeping Sickness Commission in 1908, and special research officer on kala-azar in 1911. Much of the research work he carried out in Bombay was on plague, but his most noteworthy discovery was that the spirillum of relapsing fever, which is common in Bombay, is transmitted by the bites of body lice. He was also associated with Col. Hamilton Fairley in important work on the dietetic treatment of sprue and also worked at dysenteries, enteric fever, and schistosomiasis. During a period of leave he passed the M.R.C.P., and in 1919 was elected to the Fellowship for his researches; he became an M.Sc. Bristol in 1916 and D.P.H. in 1925. He also saw military service in Baluchistan and served during the war of 1914-18, when he was twice mentioned in dispatches and received the O.B.E. In 1920 he held the professorship of pathology at Calcutta for a short time; in 1921 he became Director of the Pasteur Institute in Assam; and in 1923 he was appointed Director of the Haffkine Institute, Bombay, where so much of his earlier work had been done. Among senior administrative posts he officiated as Public Health Commissioner, Government of India, in 1928, Surgeon-General with the Government of Bombay in 1929, and Director of the Pasteur Institute and Research Laboratory, Shillong, in 1931. He also held the appointments as Honorary Surgeon to H.M. the King and to the Viceroy of India. On his retirement under the age rules Col. Mackie soon found scope for his abilities, first as pathologist at the London School of Tropical Medicine and soon after as chief medical officer to the British Overseas Airways Corporation, and he worked at the fumigation of planes to destroy the

yellow-fever-carrying mosquitoes. His great abilities and painstaking and most reliable work placed him in the forefront of medical research workers in India.

Correction

A typing error in the obituary notice of Capt. S. C. H. Hood (July 15, p. 97) gave the date of his death as July 13 instead of June 13.

Universities and Colleges

UNIVERSITY OF MANCHESTER

At the last meeting of the Council the Vice-Chancellor announced the offer of £5,000 from the Governors of the Royal Manchester Children's Hospital towards the foundation of a Child Health Institute. This offer is the first promise received since a conference was recently held in the University to consider the establishment of an Institute of Child Health. The conference was attended by representatives of some of the local authorities, the voluntary hospitals, and other institutions interested in child health. The Vice-Chancellor explained that the cost of a professorial department in this subject would be from £7,000 to £10,000 per annum, and that the establishment of the department would depend on the provision of the necessary funds from outside sources. The proposal had been met by a most encouraging response from those present at the conference, who had promised to raise with the various bodies they represented the question of annual grants for this purpose.

Dr. G. Bridge of Preston has made a gift of £10 per annum, to provide a prize in obstetrics in the Final M.B., Ch.B. examination.

UNIVERSITY OF SHEFFIELD

The Council of the University received on July 14 from Sir Arthur Hall, M.D., F.R.C.P., a volume of personal reminiscences and an album of photographs illustrating the development of the Sheffield School of Medicine since its inception. The Council accorded its warm thanks to Sir Arthur Hall for this gift.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council held on July 13 Sir Alfred Webb-Johnson was re-elected President and Sir Girling Ball and Mr. C. Max Page Vice-Presidents. Mr. R. Milnes Walker was elected a member of the Court of Examiners for a period of three years from August 3 next.

The following appointments were made for the ensuing year:

Hunterian Professors.—Mr. Cecil A. Jell, one lecture on Conservative Surgery of Carcinoma of the Rectum and Recto-sigmoid; Mr. T. B. Layton, two lectures on the Inflammations of the Middle-ear Cleft: considered Clinically, Pathologically, and Therapeutically from the Individual and National Standpoints; Surg. Capt. Lambert C. Rogers, one lecture on Ligation of Arteries; Mr. D. M. Stern, one lecture on the Aetiology and Treatment of Prolapse with Special Reference to Cystocele and Stress Incontinence; Major H. S. Shucksmith, one lecture on Abdominal Injuries in Battle Casualties; Clinical Aspects in 100 Personal Cases; Squad. Ldr. T. Cradock Henry, one lecture on Aviation Injuries of the Face; Miss Jean M. Dollar, one lecture on the use of Plastics in Ophthalmic Surgery; Squad. Ldr. D. N. Matthews, one lecture on Storage of Skin for Autogenous Grafts; Mr. Andrew K. Monro, one lecture on the Treatment of Acute Appendicitis; Mr. James Patrick, one lecture on a Study of Supination and Pronation, with Special Reference to the Treatment of Forearm Fractures; Mr. A. S. Aids, one lecture on Injuries of the Pancreas and their Surgical Treatment.

Ames and Gale Lectures.—Prof. Francis Davies, one lecture on the Early Development of the Human Embryo; Dr. D. V. Davies, one lecture on the Synovial Membrane and the Synovial Fluid of Joints; Mr. J. T. Chesterman, one lecture on Some Alterations of the Neuromuscular Balance of the Intestine and their Clinical Significance.

Erasmus Wilson Demonstrations.—Mr. L. E. G. Norbury, O.B.E., one demonstration; Mr. R. Davies-Colley, C.M.G., three demonstrations; Mr. C. E. Shattock, one demonstration; Mr. Timothy M. Tyrrell, one demonstration with ophthalmic pathological material.

Arnott Demonstrator.—Prof. A. J. E. Cave, six demonstrations.

The fifteenth Macloghlin Scholarship was awarded to S. T. H. H. Pitbeam of Lewes County School. Dr. F. K. Sanders and Mrs. H. P. Herbert were re-elected Leverhulme Research Scholars. Votes of thanks were given to Mrs. Crile for a representative collection of works of the late G. W. Crile, to Dr. W. Loudon Strain for a gift of more than 100 books, and to Miss C. F. Thompson for pamphlets and medals from the collection of her father, the late C. J. S. Thompson.

Diplomas

A Diploma of Membership was granted to Peter Hausell. Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN PUBLIC HEALTH.—Leonora A. Crawford, C. E. Jamson, Susan M. Tracy, R. K. W. Yanz.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—R. S. Allison, T. H. B. Gladstone, A. Goldberger, R. R. H. Mitchell, H. J. O'Loughlin, F. Reitman, A. M. Stearn-Wallace.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—M. M. A. Cader, E. H. M. Foxen, L. E. Gardner, A. G. Gibb, J. B. Sugden.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

A quarterly meeting of the College was held on July 18, the President, Dr. A. Fergus Hewat, in the chair. Dr. J. Colin Caird (Edinburgh), Dr. T. A. MacGibbon (Thetford, Norfolk), Dr. T. McL. Galloway (Carlisle), Dr. W. D. Henderson (Woking, Surrey), and Dr. H. P. Tait (Edinburgh) were introduced and took their seat as Fellows of the College. Dr. W. F. Brown (Ontario, Canada) and Dr. R. Maxwell Johnstone, M.C. (Edinburgh) were elected Fellows.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examination, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., and L.R.F.P.&S.Glasg.: D. J. Alexander, G. A. F. Bain, J. Bates, W. A. Benson, J. M. Blyth, T. Bowden, A. A. Bradley, J. McD. Cairns, F. J. Clarke, T. Dibdin, F. F. Dougall, A. J. K. Finlayson, S. Freedlander, Joan E. Gray, S. Harris, J. Hendrie, Helen W. Kerr, A. S. Little, G. B. Macaulay, W. McIntyre, T. G. McKendrick, A. S. A. Monem, J. McC. Murdoch, A. J. Neil, W. A. Robson, S. R. Shaw, Dorian S. Smith, J. A. Smith, Fanny Stang, D. Sweeney, V. P. Vohra, J. T. Weir, J. H. White, H. W. Woolner.

Medical Notes in Parliament

White Paper Legislation

Sir HENRY MORRIS-JONES on July 20 asked the Minister of Health whether, in view of the general misgiving about the White Paper proposals on a National Health Service, expressed in recent months by many local authorities, voluntary hospital associations, and the medical and allied professions, he would postpone the introduction of legislation pending further discussion in the House, or until after a general election. Mr. WILLINK did not think that there was any general desire or that it was the wish of the House that the Government should depart from the procedure previously announced, which assumed a stage of full discussion with the professional and other organizations concerned, followed by the submission of legislative proposals.

Flying-bomb Casualties

On July 18 Sir HENRY MORRIS-JONES asked the Home Secretary when he intended publishing the number of casualties from flying bombs and what period the statement would cover. Miss WILKINSON referred to the statement covering the month of June which was published on July 14. Similar statements would be published for succeeding months. Replying to Mr. Douglas, Miss Wilkinson said that the figures for June related entirely to casualties caused by flying bombs; there were no casualties through piloted aircraft. On security grounds the Government thought it would be undesirable if they published separate figures for casualties from piloted and from non-piloted aircraft. It would tell the enemy too much. The figures covered all casualties from non-piloted aircraft, both Service and civilian.

Evacuation from London

From July 2 to July 20 over 170,000 women and children were evacuated from London in organized parties. Mr. Willink remarks that considering the large numbers involved and the speed of the operation, it has been effected with a smoothness that reflects credit on all concerned. Some difficulties have inevitably occurred, but the reception in the safer areas has on the whole been very satisfactory. He urges upon those who have been evacuated to safer areas that they should remain there.

Penicillin for Prisoners of War.—Sir JAMES GRIGG, replying on July 18 to Mr. Robertson, said that small quantities of penicillin were being sent through the agency of the British Red Cross Society to selected medical officers for the treatment of specified patients in hospitals in enemy countries where our prisoners were.

Claims for an Arthritis Treatment.—Mr. E. P. SMITH asked on July 13 whether the Minister of Health knew that arthritis had been successfully treated with "erron," a derivative of ergosterol, at the Cook County Hospital, Chicago. Mr. WILLINK said his information was that the claims made for the product called "erron" in the treatment of arthritis were not accepted by the most authoritative medical opinion in the United States, and that clinical evidence over some seven years past did not warrant the belief that it had beneficial effects.

Diagnosis of Smallpox.—Mr. WILLINK stated on July 14 that he had arranged to issue to all medical officers of health a statement showing what condition justified a diagnosis of smallpox, and what differences should be noted between a case of smallpox and other diseases.

Medical News

The Council of Epsom College will shortly proceed to award St. Anne's Scholarships to girls attending Church of England schools. Candidates must be fully 9 and under 16 years of age, and must be orphan daughters of medical men who have been in independent practice in England or Wales for not less than five years. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected. Forms of application can be obtained from the Secretary's Office, Epsom College, Epsom, Surrey, and must be completed and returned by Oct. 15.

The American Association for the Advancement of Science will hold its annual meeting for 1944 at Cleveland, Ohio, from Sept. 11 to 16. Two previous annual meetings have been cancelled at the request of the U.S. Office of Defense Transportation.

A plan of the organization of medical services in UNRRA in both the European region and in Washington has just been issued. In the European region there is a standing technical subcommittee on health (chairman, Dr. Melville Mackenzie) comprising fourteen accredited representatives of the national health administrations of member Governments. This has three expert commissions: one on quarantine and one on health problems of displaced persons (chairman of both is Dr. P. G. Stock); and a third on nutrition under the chairmanship of Sir J. C. Drummond. The Health Division Staff of UNRRA includes: Dr. Andrew Topping (Director of Health), Dr. Neville Goodman and Dr. Dudley Reekie (Deputy Directors), and Drs. G. Stuart, G. Johnstone, F. Daubanton, and R. Coigny (medical officers). In addition the following have been appointed to the field staff (medical): Dr. J. J. Paterson, Dr. H. Stanley Banks, Dr. J. Balfour Kirk, and Dr. K. W. C. Sinclair-Loutit.

Dr. Walter B. Cannon, professor emeritus of physiology, Harvard Medical School, has been appointed visiting professor of physiology at the New York University College of Medicine.

The Army Council has given permission for Col. M. Stoddart-Scott, T.D., M.D., R.A.M.C., Creskeld Hall, Arthington, Yorks, to be announced as prospective Conservative candidate for the Pudsey and Otley Parliamentary Division of the West Riding of Yorkshire.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there were only small variations in the trends of infectious diseases. There were 57 fewer cases of whooping-cough than last week, and 47 of scarlet fever, but measles went up by 68.

Diphtheria notifications were 7 fewer than last week's low record. The largest decline in the incidence of scarlet fever was in Essex, where 30 fewer cases were recorded. The local trends of whooping-cough fluctuated: Essex had 84 fewer cases than last week, and Warwickshire 38; but Kent had 42 more, Gloucestershire 41 more, and Hertfordshire 40 more. There were 37 fewer cases of measles in Kent and 39 in Staffordshire, but 42 more in Wiltshire and 34 more in Essex. One-fifth of the total cases of measles were recorded in Lancashire.

Dysentery notifications numbered 132—3 fewer than in the preceding week. The increase in Glamorganshire from 12 to 25 cases was the only local rise of any size. The largest of the other returns were Lancashire 20, and Surrey 12.

In *Scotland* there was a general decline in the incidence of infectious diseases—96 fewer cases of measles, 48 fewer of whooping-cough, 47 of dysentery, 45 of diphtheria, and 23 of scarlet fever. Both diphtheria and dysentery were at the lowest level during recent months. Almost one-third of the total of diphtheria notifications, 29 out of 91, were recorded in Glasgow. The largest returns for dysentery were Glasgow 14, and Edinburgh 13.

In *Eire* the incidence of measles remained high. The largest return was from Clare, Ennis U.D., with 129 of the 210 cases. There was a small rise in the notifications of diphtheria and whooping-cough, three-quarters of the cases of the latter being in Dublin C.B. The 62 cases of diphtheria were spread over thirty-five registration areas.

In *Northern Ireland* the notifications of measles fell from 55 to 29, but those of scarlet fever rose slightly, from 45 to 52. Only 13 cases of diphtheria were notified, the lowest total for two months.

Week Ending July 15

The returns, of infectious diseases in England and Wales during the week included: scarlet fever 1,394, whooping-cough 2,323, diphtheria 491, measles 2,536, acute pneumonia 437, cerebrospinal fever 59, dysentery 156, paratyphoid 7, typhoid 8.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 8

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable diseases in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: Anulogy Weicent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: Anulogy Weicent, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: Meducera Weicent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumhugh Gardens, Edinburgh.

ANY QUESTIONS?

Haemorrhage after Gastro-jejunostomy

Q.—A man now aged 58 had, at the age of 30, a gastro-enterostomy for duodenal ulcer. He kept in good health until the age of 52, when he had recurrence of dyspepsia. Five months ago he had a severe haemorrhage, mostly in the form of melaena, but also with some vomiting of dark blood. I should be glad of answers to the following questions in relation to this case: (1) Is there any means of telling whether the haemorrhage was from the original ulcer or from a new one on the stoma (peptic) or a new one in the duodenum? (2) Does it make any difference to the treatment where the site of the ulcer is, and, if so, what? (3) Have there been any recent advances in treatment beyond the usual dieting, etc., and the taking of magnesium trisilicate between meals? (4) Is the taking of vitamin A really helpful in healing the ulcer, and is the taking of vitamin C in tablet form (ascorbic acid) undesirable?

A.—Haemorrhage with or without indigestion after gastro-jejunostomy for duodenal ulcer almost always comes from the anastomotic margin and not from the duodenum. In the absence of indigestion it may be from acute ulcers associated with marginal gastro-jejunitis; when indigestion is present, it is likely to be from a chronic gastro-jejunal or jejunal ulcer. The treatment is similar to that of duodenal ulcer, but rest in bed with hourly feeds, with or without magnesium trisilicate or aludrox and atropine, must generally be continued for an even longer period, generally 6 to 8 weeks instead of 4 to 6 weeks. After this the patient must remain permanently on a suitable post-ulcer regime, the most important feature of which is the taking of food at intervals of not more than 2 hours throughout the day. Additional vitamins do not hasten recovery, but when fresh orange or tomato juice is not available 50 mg. ascorbic acid dissolved in milk should be given on account of the deficiency of the diet in vitamin C.

Tenderness after Shaving

Q.—In these days of make do and try-to-sharpen safety razor blades, what is the most effective treatment of the facial skin (especially of that of the tender upper lip) before and/or after shaving?

A.—A brushless shaving cream may be substituted for soap, or an electric razor used if obtainable. Zinc cream as a basis for calamine lotion, used after shaving, will probably be found curative.

Liver Stores and Ketosis

Q.—Is there any evidence that, in the absence of starvation, emotion or exertion or excitement can deplete the liver of glycogen so completely that there is not much left for conversion into blood sugar? A short biochemical explanation of ketosis, which is fairly common in children, would be of interest.

A.—The glycogen content of the liver depends upon input and output balance, and upon nervous and endocrine controlling factors. It is undoubted that sympathetic activity associated with emotion, excitement, or exertion may cause a temporary decrease in the glycogen stores. If, however, adequate food intake is maintained (which is not always the case under these conditions) it is improbable that the sympathetic activity could be sufficiently prolonged to maintain a state of glycogen depletion. The effect of emotion, excitement, or exertion on the complex interrelationships between insulin and the pituitary and adrenal cortical hormones is not known. The generally accepted view of ketosis is that the major source of ketonic bodies is fat. If the proportion of carbohydrate to fat being burnt is lowered, there appears to be difficulty in the combustion of aceto-acetic acid. The accumulating aceto-acetic acid is decarboxylated by reductases to form beta-hydroxy-butyric acid and by decarboxylases to form acetone.

Imbalance between carbohydrate and fat may occur due to exogenous factors, such as a high fat diet, or to endogenous causes,

such as depletion of carbohydrate stores in starvation, lack of insulin with consequent interference with carbohydrate oxidation, or to excessive mobilization of fat as by ketogenic hormones. Ketones may also arise from other sources than fat, such as the non-nitrogenous residue of aromatic amino-acids. In ordinary cases of ketosis found in clinical practice, however, it is probable that an upset of fat and carbohydrate metabolism is the main underlying cause.

Hallucinations and Heart Failure

Q.—In two cases of decompensated heart failure, hallucinations of a vivid and realistic character developed, and not many days after their first appearance both patients died. How is the occurrence of these hallucinations to be explained, and are they of any prognostic significance?

A.—Hallucinations of all kinds are liable to appear when the functions of the cortex are interfered with. Deficient oxygenation of the blood is one of the commonest causes of such an interference, and seems to be particularly common in the causation of visual hallucinations. For instance, many perfectly healthy people have vivid visual hallucinations, of the unreality of which they are aware, in the half-dreamy state before going off to sleep (hypnagogic hallucinations). Some people can even entertain themselves with a sort of automatic cinema-show before dropping off. In the patients referred to, the appearance of the hallucinations was the sign of an increase in cardiovascular inefficiency, and so could be legitimately regarded as of bad prognostic significance. In these patients there may have been also other signs of impaired cortical function—e.g., some failure of memory for recent events or of the power of concentration.

Treatment of Anxiety Symptoms

Q.—A man of 31, suffering from anxiety symptoms consisting mainly of excessive nervousness and tremulousness in company, apparently the result of unknown factors originating in early childhood, has been advised to undergo a course of electric shock treatment. Present circumstances make it impossible for him to undergo a prolonged analysis, and it is suggested that shock treatment, though not a cure, may somewhat alleviate the symptoms. He is an intelligent type, whose interests are mainly on mathematical and other intellectual lines, and his fear is that the treatment may impair his faculties. Though not entirely disabling, his condition is distressing because it cuts him off from social contacts and is a serious handicap in his career, and he is therefore quite willing to face the risk of fractures, which have been mentioned as a possibility. What advice can be given as regards risks, immediate and late? Presumably shock therapy would not interfere with analytical or other treatment at a later date.

A.—Electrical convulsion therapy is not desirable. The evidence that it helps this class of condition is practically nil, and its administration here would be the purest empiricism. The possibility of such treatment injuring intellectual powers must always be borne in mind. Psychotherapy of an intensive sort is the correct treatment, and it may not prove to be a prolonged matter.

Galactorrhoea

Q.—Could you suggest treatment for a serous discharge from both nipples of a patient who has been so afflicted for eight years, since an unsuccessful pregnancy (premature stillbirth)? Hormone therapy has been unsuccessful. At no time has there been blood. There is no apparent mastitis.

A.—The history suggests that the discharge is due to a persisting secretory function of the mammary glands and that it is either milk or analogous to it. Galactorrhoea, as this symptom is called, is rare, but extraordinary examples have been recorded from time to time through the centuries, sometimes even in virgins and men. It can result from lesions in the pituitary gland or the adjacent parts of the brain, and in particular is associated with acromegaly. Ovarian tumours such as lutein cysts have also been reported as causing it. It sometimes follows ovarian failure and has been described as a cyclical phenomenon coinciding with, or replacing, menstruation. The above possibilities should be excluded, but a more simple explanation should be kept in mind. Lactation can be maintained almost indefinitely by local stimulation of the breasts, and if the patient is continually attempting to express the discharge to confirm its presence, that might be enough to account for its persistence.

If a cause cannot be found, treatment is difficult. The breasts should be well supported by a brassiere and all forms of manipulation avoided. Assuming that it is oestrogenic hormone therapy which has failed, it would be worth while trying the effect of androgens, either testosterone propionate intramuscularly or methyl testosterone sublingual tablets. The dose will be a matter for trial, but large amounts may be required. Alternatively, ethisterone might be helpful. Iodine and iodides have also been used, apparently with good effect in some cases.

Aniline Poisoning

Q.—(1) Is it known what abnormal compound of haemoglobin exists in the blood in cases of anilism in those cases of poisoning by aniline or its compounds, and in the particular case of T.N.T.? (2) Is this compound formed by direct combination in the alveoli of the lungs when fine dust or fumes of T.N.T. are inhaled, or is it formed by the action on the blood of T.N.T. absorbed through the skin, or by both channels? (3) Is the bone marrow affected in these cases of anilism, and, if not, why does cyanosis persist for several weeks when cases are removed from contact. (4) Can the abnormal haemoglobin compounds carry any oxygen whatever? (5) Does toxic hepatitis play any part in the production of cyanosis in cases of anilism?

A.—(1) The compound formed is chiefly methaemoglobin, with possibly some nitrohaemoglobin. (2) These compounds are formed by the action of T.N.T. on the blood after absorption through both skin and lungs, and possibly to some extent by ingestion. (3) In cases of pure anilism, without the rarer incidence of true aplastic anaemia, there is usually a depression of red-cell elements, with a consequent anaemia, accompanied by a fall of haemoglobin. True aplastic anaemia may be a feature of T.N.T. poisoning without cyanosis. (4) Methaemoglobin and nitrohaemoglobin carry no oxygen, but it must be remembered that only a certain percentage of haemoglobin is converted into these abnormal compounds. (5) Toxic hepatitis has no direct connexion with cyanosis, but the liver, the bone marrow, and the haemoglobin may be attacked simultaneously as well as separately.

Tap Water and Blood Transfusion

Q.—A blood transfusion was done on a patient. Tap water was used for rinsing and boiling rubber tubing, needle, and glass tube. The patient had a severe reaction during the transfusion and was quite ill for 48 hours. The transfusion was of fresh blood and was cross-matched. Was his reaction due to the tap water used? Is freshly distilled water now always used, even at the front? Are many people so allergic to tap water? Do these reactions occur even in glucose-saline transfusions if tap water is used?

A.—It is maintained by certain workers that London tap water can be used for rinsing and cleaning transfusion apparatus. The Emergency Transfusion Service would not use the tap water for rinsing and boiling rubber tubing, needle, and glass tube unless the apparatus was subsequently dried and autoclaved. It is possible, of course, that a small amount of dried protein from previous transfusions remained in the apparatus, but the most likely explanation of the reaction is the use of tap water. At the front dry sterilized apparatus is provided. I should expect reactions to occur in glucose-saline transfusions if tap water were used, but know of no evidence on this point.

Sunlight and Tuberculosis

Q.—Is sunlight, artificial or natural, harmful in cases of active pulmonary tuberculosis? Can it be given with safety in gradually increasing doses? Is it the case that those people who tan as the result of exposure to the sun will not derive any harm from this practice, and vice versa? What is the position with regard to tuberculosis of other regions?

A.—The use of sunlight, artificial or natural, is dangerous in active pulmonary tuberculosis. Its value is rather problematical and is outweighed by the danger unless prescribed by an expert. It is not the case that those people who tan easily as a result of exposure to the sun will derive no harm from this practice, though they are less likely to do so. The use of carefully graduated doses of sunlight in cases of bone-and-joint, glandular, and peritoneal tuberculosis is very valuable, but the best results will be obtained by those with experience. The questioner is recommended to consult *Actino-Therapy* by Rollier for details.

Cysts of Buccal Mucous Glands

Q.—For the past nine months a patient has had recurrent cysts of the buccal mucous glands. The condition was limited to the inside of the lower lip to the left of the midline—approximately over the distribution of the terminal branches of the left mandibular nerve. Recently the opposite side has been affected also. The cysts periodically break, liberating a clear fluid which shows nothing microscopically. Many local treatments and attention to general health have been tried with no improvement. Occasionally only, say, six cysts are present, sometimes many more.

A.—Cysts of the muciparous glands of the lips are not uncommon. They are retention cysts, and when recurrence occurs, as in the present case, trauma, lip-biting, or incomplete removal should be suspected. The treatment is surgical. Single cysts can be shelled out individually, but when there is a general cystic condition of the glands a flap should be turned back and the mass dissected out.

INCOME TAX

Assistant

"X. Y. X." employed an indoor assistant at £450 a year, but he has recently become an outdoor assistant receiving an additional £104, making £554 a year. (a) If he is paid the £104 separately to meet the rent he will have to pay will the £104 be exempt? (b) His new house will be used for professional purposes; what expenses can the assistant claim for this?

** (a) No; the £104 is assessable to income tax and is liable to deduction of tax under "pay as you earn." (b) Assuming that the assistant is required by the conditions of his employment to use his house for professional purposes, he can claim to deduct a reasonable proportion of the general cost of the house, rent, rates, lighting, etc. What a reasonable proportion would be must of course depend on the particular facts.

LETTERS, NOTES, ETC.

Sterilization of Syringes

Dr. E. H. ROBERTS (Hythe, Southampton) writes: I have been in the habit of keeping my syringe in its container in 50% "dettol." I change the needle when it is blunt and the dettol every fortnight. For some years I did not disinfect the skin (I do now with the dettol in the container for the patients' benefit and to be on the safe side). I carry out this method for all kinds of injections—mainly T.A.B., T.A.F., A.P.T., whooping-cough vaccine, etc. If I do what I call a "dirty" injection, I then change the needle and soak the syringe in pure dettol for half an hour. After using my syringe for a fortnight in this way I had the dettol in the container and an injection of sterile saline, which I sucked up in the syringe, cultured (2 of each). These showed growth of *B. subtilis*, no other organisms being found. *B. subtilis*, I understand, is regarded as harmless to man on injection. I have used this method for ten years for several thousand injections with, so far, no ill effect. It is labour-saving and, I hope, is fool-proof.

Offers of Hospitality for Doctors' Children

The following additional offers have been received from doctors willing to accommodate the children of colleagues practising in dangerous areas. Dr. A., who practises in a village in Lincolnshire, could take two children, preferably girls, for the period of the school holidays, or longer if necessary. He has two daughters aged 15 and 9, who will be returning to school towards the end of September. Alternatively, Dr. A. offers to accommodate a doctor and his wife, or to exchange practices for a fortnight with a doctor in the London area. Dr. B., of Birmingham, offers accommodation for two boys, preferably Scottish. Dr. C., who is in practice near Plymouth, has a daughter of 10 and offers to accommodate a girl between the ages of 9 and 11 for the holiday period. Dr. D., of Sheffield, who has a young daughter, would be glad to accommodate two children, preferably over 10 years of age. Dr. E., practising in Cornwall, offers to take a child over 7, either a boy or a girl; he has three children of his own. Any readers interested in these offers may communicate with the Secretary at B.M.A. House, Tavistock Square, W.C.1.

The Flying Bomb: Exchange of Duties

A doctor living in the North in "country surroundings that are particularly attractive just now" writes to suggest that "we doctors who live in safe areas should be allowed to take our turn at the casualty services and give our overstrained colleagues in London a much-needed rest by changing places for a few weeks." He asks if it could be arranged for him to do his share during the present flying bomb attacks. He has already been put in touch with a London colleague, but we publish his suggestion as there may be others who would like to follow his example.

Baby wanted for Adoption

Dr. E. W. DEWEY (214, London Road, Portsmouth) writes: I wonder if any of your readers know of a baby requiring adoption. The child should be a boy, between 2 and 6 months, healthy, and of good stock, and preferably resident somewhere in the South of England. I should be glad if anybody knowing of such a child would communicate with me.

Correction

Dr. ARTHUR F. COCA (New York), whose letter on vitamin B deficiency in allergic patients appeared last week (p. 128), asks that the following should be substituted for the last sentence of paragraph 2—that is, after the word "prescribed": "The daily dose required for complete relief of the symptoms of B deficiency is from four to seven cakes of Fleischmann's standard yeast." In a covering letter Dr. Coca comments that "the small dose of one and one-half cakes of yeast was satisfactory only with a supplemental small dose of liver extract."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY AUGUST 5 1944

PENICILLIN: A SURVEY*

By

Sir H. W. FLOREY, M.B., Ph.D., F.R.S.

Professor of Pathology, University of Oxford

The chemotherapeutic properties of penicillin were discovered in 1940, but before this there was a long history which for convenience can be divided into stages. (1) The discovery of naturally occurring antibacterial substances—or antibiotics, as they are now beginning to be called—and the early attempts to utilize them in medicine. (2) The discovery of the antibacterial substance penicillin by Alexander Fleming. (3) The discovery of its chemotherapeutic properties at Oxford. (4) The development in which we are at present, which consists of three interrelated lines of research—namely, (i) exploration of methods for mass producing penicillin by the growth of the mould *Penicillium notatum*, (ii) investigation of the chemical nature of penicillin with the hope that it may eventually be synthesized by chemical means, and (iii) the clinical exploitation of the known properties of penicillin.

Stage 1

We have to go back to 1877 for the first observation of a naturally produced antibacterial substance. In that year Pasteur and Joubert described how when common air bacteria contaminated flasks of broth containing the bacillus of anthrax the growth of the anthrax bacillus was stopped. That phenomenon was probably the first observation that one organism may produce a chemical substance—or antibiotic—which is capable of stopping the growth of another, though Pasteur did not realize its true significance. In the succeeding years many examples were discovered, of which the most interesting was *Bacillus pyocyaneus*. From the medium on which this organism had grown Emmerich and Loew extracted a substance which they called pyocyanase. This was found to be capable of stopping the growth of certain organisms causing disease, notably anthrax and diphtheria. They applied it to the lesions of the skin caused by anthrax with, they claimed, some benefit. Although this product was on sale in Germany as recently as the 1930s its use in medicine never became widespread.

Stage 2

In 1928 Fleming was studying the staphylococcus. One day he examined and then put aside on his bench a plate on which colonies of the staphylococcus were growing. Several days after there was a colony of mould growing on one side. Fleming noticed that in the neighbourhood of the mould the colonies of staphylococci were disappearing. He recognized this as a phenomenon of interest, and subcultured the mould, which was later identified as *Penicillium notatum*. When grown on nutrient broth it was found to produce some substance which passed into the liquid. By experiments in test-tubes Fleming showed that the liquid had the property of stopping the growth of many bacteria. Fleming called the active liquid penicillin. He carried out experiments on the effect of his broth on numerous organisms in test-tubes and showed that many which can cause disease in man were affected, although disease-producing organisms were quite insensitive. He

also injected some of the broth containing penicillin into rabbits, and found that it was no more toxic than ordinary broth. He found, too, that the broth did not harm the white blood cells. Fleming, who had been working on antiseptics, recognized that penicillin had some very desirable properties as an antiseptic, and proposed that it might be useful for local application to infected surfaces. He did, in fact, so apply it in a few cases, with results indicating, as he said, that "it certainly appeared to be superior to dressings containing potent chemicals." About this time an attempt was made by Clutterbuck, Lovell, and Raistrick to extract the penicillin. They succeeded in growing the mould on a purely synthetic medium and found that the active substance could be extracted into ether when the watery medium containing penicillin was acidified. However, when they tried to concentrate the penicillin by evaporating the ether most of the activity was lost, and they concluded that penicillin was "extremely labile."

We may briefly summarize the position at the end of this phase by saying that Fleming had discovered the existence of an antibiotic produced by *Penicillium notatum*. Some test-tube investigations had been made of the antibacterial power of the crude broth and, as a result, it had been suggested that it might be useful as an antiseptic locally applied to infected lesions. But as the result of both Fleming's and Clutterbuck, Lovell, and Raistrick's work the conclusion had been reached that penicillin was an unstable substance and therefore unlikely to have any practical value in medicine.

Stage 3

Stage 3 deals with the work done at Oxford. My own interest in the phenomena of bacterial inhibition began in the 1920s. Since 1929, at first alone and later with collaborators, work had been in progress, but it was not till 1938 that Dr Chain, a biochemist, and I prepared a plan for the systematic study of some of the naturally produced antibacterial substances. After much discussion the choice was narrowed down to three—*Bacillus pyocyaneus*, *Penicillium notatum*, and the subtilis mesentericus group of bacteria. Eventually work was undertaken on the first two. Miss Schoenthal obtained three antibacterial products from *Bacillus pyocyaneus*, which all proved to be very toxic, but fortunately the results with penicillin turned out rather differently.

Both Fleming and Clutterbuck, Lovell, and Raistrick had noticed that under certain conditions the crude broth might retain its activity for at least several weeks. This indicated that in appropriate conditions the substance might not be so unstable as had been pictured. To work on the metabolic products of moulds from biological as well as chemical aspects needs a team of specialized workers, so that the various fields of investigation may be covered, and it was most fortunate that such a team was available in Oxford at that time. I should like to stress that this work could not have been carried through had it not been for the unremitting labours of the following people: Dr Chain, Dr Abraham, Prof Gardner, Dr Heatley, Dr Jennings, Dr Sanders, Dr Fletcher, and Lady Florey. Nor

*Abridgment of the Peter Le Neve Foster Lecture delivered before the Royal Society of Arts on June 7, 1944.

could we have got far without the work of our technical assistants, Mr. Glistler and his "penicillin girls," Mr. Kent, and, for the chemical work, Mr. Callow and Mr. Burt.

The body of work done by this team in the next two years produced a single end-result—penicillin as a proved chemotherapeutic drug. The steps cannot be set out chronologically because different aspects of the work were in progress simultaneously, and the accent was first on one thing and then on another until a fairly complete picture was built up. The first step in all work of this type is to grow the mould on a medium into which it will produce the active substance. Here we were able, in the first place, to use the information which had been obtained by Fleming and by Clutterbuck, Lovell, and Raistrick, and we began by growing the mould on the synthetic medium proposed by the latter workers.

In studying an antibiotic its fundamental property of inhibiting bacteria can be made use of as a test method, and we owe to Dr. Heatley the elaboration of a test which has proved invaluable for work not only on penicillin but on many other antibiotics as well. By means of his method it was possible to follow the various fractionating processes. The crucial chemical observation was the demonstration that not only did penicillin, when made acid, pass from a watery into an organic solvent such as ether or amyl acetate, but that it could be recovered from the organic solvent when shaken with water and an appropriate amount of alkali. By repetitions of this process purification and concentration were effected and the first stable products containing penicillin produced.

Chemical Properties of Penicillin

The principal chemical properties of penicillin are these: (1) An acid, unstable in the acid form but stable as salts between pH 5 and pH 7. (2) Ba, Ca, and Na salts highly soluble. (3) Destroyed by acids and alkalis and by heating. (4) Inactivated by oxidizing agents, heavy metals, primary alcohols, and ketonic reagents. (5) Inactivated by enzymes produced by some common bacteria.

This last is a very important observation, because it explains why large-scale production has proved to be more than usually difficult. The ubiquitous air bacteria may produce ferments which destroy the penicillin as fast as the mould makes it, so that although the mould may appear to grow well no penicillin is produced. As a consequence, all penicillin has to be manufactured with the exclusion of all air bacteria, and to do this on a large scale is a very difficult technical feat.

The production of a partly purified extract made possible the biological investigations which formed the next stage. It was found that the extract, even when highly diluted, would stop the growth of many organisms causing disease.

Bacteria Sensitive to Penicillin

Gram-positive.—*Streptococcus pyogenes*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus viridans*, *Bacillus anthracis*, *Corynebacterium diphtheriae*, *Actinomyces bovis*, *Clostridium tetani*, *Cl. welchii*, *Cl. septicum*, *Cl. oedematiens*.

Gram-negative.—*Neisseria gonorrhoeae*, *N. meningitidis*.

Bacteria not Sensitive to Penicillin

Relatively insensitive.—Gram-negative: *Salmonella typhi*, *S. gaertneri*, *Vibrio El Tor*.

Almost or completely insensitive.—Gram-positive: *Mycobacterium tuberculosis*. Gram-negative: *Pasteurella pestis*, *Vibrio cholerae*, *Bacterium coli*, *Pseudomonas pyocyanea*, *Proteus*, *Brucella abortus*, *Br. melitensis*, *Bacillus of Friedländer*.

This list is substantially the same as Fleming found with his crude broth containing penicillin, with the important addition among the sensitive organisms of the bacilli of gas gangrene and, unhappily, among the insensitive of the tubercle bacillus. Only those diseases caused by sensitive bacteria are susceptible of cure by penicillin. It was shown that penicillin, except possibly in very strong solution, does not kill the bacteria, but is a bacteriostatic. The penicillin preparations which we had at that time were bacteriostatic for sensitive bacteria at the dilution of 1 in 1 million, but we now know that these were very impure products. Pure penicillin will stop the growth of some kinds of bacteria at the astonishing dilution of 1 in 50 million or more.

It was further shown that the activity of the substance was maintained with scarcely any diminution in serum, in pus, and in the presence of autolysed body tissues. During the process of autolysis many breakdown products are formed, but none of them interfere with the action of the penicillin. The properties differentiate penicillin very sharply from the sulphamide group of drugs, which are rendered largely ineffective by pus or tissue breakdown products. Another important finding was that penicillin would act almost equally well when large numbers of bacteria were present as when there were few; in either case it would inhibit the growth of the whole lot. This again is in sharp contrast to the sulphamides, which are rendered less effective if many bacteria are present.

The fact that penicillin is a very powerful antibacterial agent would not by itself differentiate it from a number of other mould products or from some of the familiar chemical antiseptics. But whereas nearly all such substances are quite toxic to body tissues, even concentrated extracts of penicillin had practically no poisonous action on animals. It was further shown that individual body cells, such as the white cells in the blood, were unaffected by concentrations many hundred times greater than those necessary to stop the growth of sensitive organisms.

When administered to an infected animal or man in sufficient quantity penicillin stops the growth of the germs, thus giving the white blood cells in particular, and possibly other defence mechanisms, the opportunity effectively to attack and destroy them. It was found, too, that tissue cultures would survive and grow in concentrations very much greater than those necessary to produce bacteriostasis. In animals the active material was rapidly excreted by the kidneys into the urine, and, to a lesser extent, by the liver into the bile. It was readily absorbed after injection under the skin or into the muscles or into the small intestine, but it could not be given by mouth because of the hydrochloric acid in the stomach, which destroys penicillin very rapidly. Neither could it be given by the large bowel, because the bacteria there destroy it.

The position at which we had now arrived was that we had in our hands a substance which combined very low toxicity to animals with a very powerful action against disease-producing bacteria. We knew a good deal about its fundamental behavior in the animal body. The most important step had now been reached—we had still to learn whether it would cure disease in animals and man.

It is worth while to digress for a moment in order to take up the question of antiseptics, so that the real significance of the experiments about to be described may be understood. Everyone is familiar with antiseptics such as mercuric chloride, acriflavine, dettol, lysol, etc. All these are capable, under appropriate conditions, of killing bacteria—mark the word "killing"—but cannot be used for injecting into the animal body because they have a damaging effect on animal cells as well as on bacteria. All the antiseptics in common use destroy the protoplasm quite quickly, and this applies equally to the protoplasm of the bacterium and of the animal. As might be expected, although antiseptics can be used for sterilizing instruments and similar purposes, little success has attended their use in dealing with infected wounds, still less their injection into the body. A chemotherapeutic agent differs from antiseptics in that it selectively attacks the organisms causing the disease without at the same time doing any serious injury to the body. For this reason it can be given internally or by injection. There are several examples of such chemotherapeutic substances. The one which has been known the longest, and is perhaps the most familiar, is quinine, used to combat malaria. Quinine is swallowed by mouth, passes into the blood stream, and exerts its beneficent action in killing the malaria parasite while being carried round to all parts of the body. Another example is salvarsan, the discovery of Ehrlich, produced after many years of work. It is an arsenic compound which has a very profound effect on the spirochaete of syphilis without being too toxic to be borne by the person suffering from the disease. Other substances were discovered which were effective against various tropical diseases, but only one class of substance, the sulphamides, had been found of any use in common diseases.

has sepsis. Their use was for various reasons—some of which have been mentioned earlier—somewhat limited. These are all true chemotherapeutic agents, not antiseptics.

The following experiments demonstrated that penicillin belongs to the class of true chemotherapeutic agents. So far as the use of penicillin in medicine is concerned this was the actual discovery. Such experiments are carried out in the following way. Mice are injected with bacteria such as *reptococci* and *staphylococci* so that they will certainly die from the infection within one or at most two days. To show that a substance suspected of having chemotherapeutic properties is active it is necessary to secure survival of a substantial number of mice which would otherwise certainly die in the case of penicillin this was accomplished by injecting some penicillin under the skins of the infected animals every three hours for several days. The drug was absorbed from beneath the skin into the blood stream, which carried it to the place where the infecting bacteria had previously been placed. Knowing that penicillin was a soluble substance quickly distributed round the body, that it was not toxic to animal tissues, and that it was just as active in the presence of body tissues as in a test tube we were justified in hoping that it would stop the bacteria growing as effectively in the body as it did outside. And this proved to be the case. The groups of treated mice survived almost without exception, while the untreated mice all died. These first experiments indicated without any doubt that penicillin belonged to that rare class of drugs which can be used as chemotherapeutic agents.

From this demonstration it appeared that penicillin was likely to have very great potentialities in the field of human medicine. Penicillin at that time was extremely difficult to produce in substantial quantities, so that some time passed before we were able to show its powers on man. We again have to thank Dr. Heatley and his assistants for unremitting work in producing in the laboratory enough penicillin for the first injections in man. Even after months of work we could treat only six cases of severe infection, but the results were most promising.

The first human patients were treated in the winter and spring of 1940-1, at the time of the worst bombing of England. It seemed improbable that much headway could be made in getting large-scale production started in this country. In these circumstances Dr. Heatley and I went to America, which was not then at war, to ask them whether they could put some of their great resources into the production of penicillin, so that more extensive clinical trials could be carried out. We were extremely fortunate in coming into contact with Dr. Coghill, Director of the Fermentation Division of the Department of Agriculture's excellent research laboratory at Peoria, in Illinois. The work which he and his colleagues have done on the selection of high yielding strains of *Penicillium notatum* and on the modification of culture media, has greatly increased the yield which can be obtained from the mould, and has played an important part in the large scale production of penicillin.

While this work was being initiated in America, enough material was made in Oxford and by Imperial Chemical Industries to enable some eighteen patients with severe infections, most of them caused by the *staphylococcus*, to be treated. These results were again of such great promise that any effort to produce the drug on a really large scale was clearly worth while. This was more so since certain of the bacteria susceptible to penicillin cause some of the most common and universal infections including those of war wounds.

Stage 4

From that time the work branched in three directions. First, it was clear that it would be very desirable to make the substance synthetically by chemical procedures without the intervention of the mould. Work is now proceeding along these lines in Oxford, where Dr. Chain and Dr. Abraham are collaborating with Sir Robert Robinson and his colleagues, and elsewhere, both in this country and in America, hundreds of chemists are engaged on this important problem. Progress in this direction cannot be reported as it is now in the secret category, but the fact has already been published that pure

penicillin has been obtained. This was done in America and in Oxford at about the same time. Every resource has been mobilized to deal with this chemical question, but whether success will attend the effort to produce penicillin by synthesis it is impossible to forecast.

The second, and more immediately practicable line, has been to increase the manufacture by means of the mould to a really large scale. This has involved a large number of intricate technical problems, which have been tackled along different lines by the various commercial firms, both in this country and in America. As a result of their efforts penicillin can now be issued by the kilogramme, although, of course, the supplies still fall lamentably short of the demand.

The third line has been to explore further the use of penicillin as a curative agent. There are two possible ways of using penicillin. First, it can be injected into the muscles or veins so that it is carried around in the circulation to the parts which are being attacked by the infecting bacteria. This method is obligatory in the more serious and widespread diseases such as pneumonia, diseases of the bones, and septicaemia, where the diseased tissues cannot be reached by any other means. Although in many cases this is a very effective method, it has the disadvantage of requiring relatively large amounts of penicillin, since the drug is rapidly excreted by the kidneys. Secondly, penicillin may be used as a local application to the affected part. This can be undertaken only if every portion of the infected tissues can be reached by the penicillin, and a good deal of the success of local application depends upon surgical ingenuity in ensuring that the penicillin, which is rapidly absorbed from a wound, is kept in contact with all the infected tissues long enough to exert its action. At the present time a great deal of thought and study is being given to the problem of war wounds and how best to utilize penicillin, both locally and generally, for their treatment.

The increasing supplies of penicillin now available permit of extensive explorations of its use in many diseases. Perhaps the most striking recent addition to knowledge is that of the Americans, who have discovered that penicillin is apparently effective in treating syphilis. Another excellent development since larger supplies have become available is that penicillin can now be given as a preventive instead of as a last resort. In battle casualties especially, the effort is being made to prevent serious sepsis from developing by giving penicillin at a very early stage.

TREATMENT OF ACUTE EMPYEMA WITH PENICILLIN

BY

E. C. B. BUTLER, F.R.C.S.

Assistant Surgeon to the London Hospital

KENNETH M. A. PERRY, M.D., M.R.C.P.

Member of Scientific Staff of Medical Research Council

AND

F. C. O. VALENTINE, M.R.C.P.

Physician in Charge of Inoculation Department, the London Hospital, Pathologist, F.M.S.

Treatment of acute empyema has both immediate and ultimate aims—the former to overcome the toxæmia by sterilizing or draining the cavity, the latter to restore the function of the lung and chest wall. This investigation is intended to show how far penicillin can assist in the realization of these aims when it is used in the simplest possible way—repeated emptying of the cavity by aspiration, followed by injection of the drug into it. Penicillin was dissolved in water to give a concentration of 1,000 units per c.c.m., and the dosage was adjusted to the size of the cavity. The sensitivity of the infecting organism having been established, the initial injection varied between 10,000 and 40,000 units, 20,000 being usual. As treatment proceeded 10,000 or 5,000 units often sufficed. Tests for the presence of the drug in the pus withdrawn provide essential guidance in this respect. In the cases in which multiple loculi were present each cavity was treated on the same lines. It

was soon found that treatment on alternate days was adequate in the ordinary case, but the presence of a broncho-pleural fistula, associated with the rapid disappearance of the drug from the pleural cavity, may render more frequent injections necessary. Our supply did not permit us to supplement local with systemic therapy, which may be desirable in some, if not all, cases.

So far, 18 cases (Table I) have been treated. They show the variations to be expected in such a series in regard to age,

Case 4

The patient, a male omnibus driver aged 53, had a right-sided empyema, the largest aspiration from which was 3 pints of pus. The infecting organism was a haemolytic streptococcus. He developed a cough 25 days before admission, followed in 3 days by pain in the right side of the chest. One week later he was admitted to Oldchurch Hospital, under Dr. W. J. Stokes, in a toxic distressed

FIG. 1.—Case 2; woman aged 60. Right empyema; pneumococcus Type 28. (Oct. 5, 1943.)

FIG. 2.—Case 2 at May 25, 1944.

FIG. 3.—Case 4; man aged 53. Right empyema after emptying cavity by aspiration. Haemolytic streptococcus. (Jan. 8, 1944.)

FIG. 4.—Case 4 at May 10, 1944.

sex, site of lesion, loculation, infecting organism, underlying lung condition, and broncho-pleural fistula, any of which may be of the greatest importance when considering the individual case. But as treatment proceeds they also tend to show certain common features, such as have been described by workers both in this country and in the United States. To illustrate this, one case (No. 4) is described below in detail, the course of the others being shown in the table and their special features discussed when necessary.

condition with signs of a large right pleural effusion, which on aspiration showed the presence of pus and haemolytic streptococci. He was treated by aspiration and 40 g. of sulphapyridine. He was still in a toxic condition when admitted to Claybury Emergency Hospital on Dec. 9, 1943. There was stony dullness, with absence of breath sounds, over the right side of the chest. This was aspirated, and thin pus was obtained from which haemolytic streptococci were grown.

Aspiration and injection of penicillin began on the day of admission, and were continued on alternate days until Jan 5, 40,000 units being given on the first day and thereafter 20,000 or 10,000 units. The pus withdrawn remained sterile on culture after the first injection, and steadily thickened until, after 14 days' treatment, the deposit on standing took up the whole volume of fluid. During this period the appearance of the streptococci as stained by Gram's method gradually changed until by the 10th day of treatment all were atypical, showing as minute Gram positive dots, often in clusters. Pus continued to collect at intervals, causing slight fever, but otherwise appearing to be of the cold abscess type, and the minute cocci, sterile on culture, persisted until Feb 24. The last aspiration, however—on April 4—withdrew 40 c cm of clear fluid containing lymphocytes. During this prolonged period radiographs

This brief account will serve to suggest certain problems that arise during the treatment described. The cavity was sterilized, but it was difficult to say when this was finally accomplished. The prolonged pus formation after sterilization of the cavity, maintaining pulmonary collapse, and increasing pleural thickening were, however, a disappointing feature.

The Remaining Cases

Table I gives details of all the cases under discussion. They include four cases of infection with haemolytic streptococci, three

FIG 5—Case 8, boy aged 10. Left empyema, pneumococcus Type 1 (Jan 23, 1944)

FIG 6—Case 8 at May 5, 1944

FIG 7—Case 10, man aged 49. Right empyema showing postero-lateral and antero-medial pockets, pneumococcus Type 2 (March 20, 1944)

FIG 8—Case 10 at May 26, 1944

taken after aspiration showed a progressively lessening cavity with thickened walls (Figs 3 and 4). At the time of writing the patient is well and back at work, but the chest wall is sunken and immobile over the affected area; however, serial radiographs show that the lung is still re-expanding.

with non haemolytic streptococci, one with a micro aerophilic streptococcus, and one with an anaerobic streptococcus. There were seven cases of pneumococcal infection and one case from which a haemolytic streptococcus was first isolated, to be followed later by a pneumococcus.

In every case, except No 17, in which there was a broncho pleural fistula, the cavity was sterilized with a dosage of penicillin ranging from 40,000 to 200,000 units, but it is not easy to determine the period of injections adequate to ensure permanent sterility. Cultures of the pus are often found to be sterile after one injection.

TABLE I.—Details of 18 Cases

No.	Sex	Age	Side	Complicating Disease	Organism in Empyema	Total Units of Penicillin	Weeks Febrile	No. of Aspirations	Most Pus Removed at Single Aspiration	Day of Final Aspiration	Present Condition
1	M	55	Right	Perforated appendix	Non-haemolytic streptococcus	40,000	2	4	18 oz.	23	After reconstruction of abdominal wall: Well. No cough; little pleural thickening. At work.
2	F	60	"	"	Pneumococcus Type 28	80,000	8	11	4 oz.	22	Well. Taking normal exercise. (Figs. 1 and 2)
3	F	71	"	"	" Type 8	40,000	4	7	8½ oz.	21	Well. No pleural thickening. Taking normal exercise.
4	M	53	"	"	Haemolytic streptococcus	270,000	9	21	60 oz.	85	Well and at work. Considerable pleural thickening (Figs. 3 and 4)
5	F	19	Left	"	"	155,000	4	10	20 oz.	18	Well and at work. Pleural thickening
6	F	28	Right	Tuberculosis R. zones 1 & 2; right artificial pneumothorax; division of adhesions. Haemorrhage; secondarily infected	Anaerobic streptococcus	155,000	12	12	13 oz.	28	Haemoglobin 70%. Blood transfusion. Now afebrile. Small effusion, which is sterile. Sanatorium
7	M	52	Left	"	Pneumococcus Type 1	80,000	1	8	11½ oz.	20	Well. Some pleural thickening
8	M	10	Left	"	"	135,000	5	13	13 oz.	49	Well; back at school. No scoliosis; no thickening July. (Figs. 5 and 6)
9	F	31	Right	Very severe rheumatoid arthritis	Haemolytic streptococcus	100,000	4	10	5 oz.	32	Well. Considerable pleural thickening
10	M	49	"	"	Pneumococcus Type 2	200,000	5	16	12 oz.	46	Well and at work. Developed antero-medial and postero-lateral pockets with marked pleural thickening in each (Figs. 7 and 8)
11	M	41	Left	"	" Type 1	95,000	2	9	24 oz.	20	Became sterile after 55,000 units, but pneumococci reappeared. Little pleural thickening. Back at work.
12	M	2	"	Streptococcal pemphigus; streptococcal bursitis over left elbow	Haemolytic streptococcus; secondarily, pneumococcus Type 19	95,000	8	5	18 oz.	—	Improved from a moribund condition, but developed broncho-pleural fistula, necessitating rib-resection and drainage, 22/4/44. Condition again deteriorated; died 20/5/44. No necropsy
13	M	59	Right	"	Pneumococcus Type 24	45,000	2	5	15 oz.	17	Became sterile after 25,000 units, but with appearance of broncho-pleural fistula became reinfected. No pleural thickening. Back at work.
14	M	21	"	Traumatic haemothorax from bullet wound	Sterile	30,000	1	6	12 oz.	14	Well. Returned to unit
15	M	52	Left	"	Non-haemolytic streptococcus	60,000	1	4	23 oz.	37	Well. Some pleural thickening
16	F	32	Right	Mural stenosis; pulmonary infarct	"	90,000	1	7	8 oz.	22	Greatly improved
17	M	52	Left	"	Micro-aerophilic streptococcus	230,000	7	8	44 oz.	—	Condition never satisfactory, as penicillin rapidly disappeared from pleural cavity probably owing to broncho-pleural fistula. 6/5/44: Rib-resection and drainage; condition continued to deteriorate. 23/5/44: Died.
18	F	70	Right	Left radical mastoid operation	Haemolytic streptococcus	60,000	1	4	23 oz.	21	Greatly improved. Some pleural thickening

f penicillin, but withdrawal of the drug at this stage would invite recurrence. Table II indicates the sequence of events in 12 uncomplicated cases—7 streptococcal and 5 pneumococcal. The table shows the period of continuous administration of penicillin in each case, the day on which the pus gave a sterile culture, and that on which all the cocci in the pus were of the abnormal small type described in the account of Case 4. It will be seen that with pneumococci the change in appearance coincides with, or follows closely, the first sterile culture, but in the case of streptococci there is a longer interval. But even with the latter organism it was found to be unsafe to use this test as an indication for stopping the injections, as the recurrence of infection in Cases 15 and 16 shows. It is noticeable that in five cases in which active infection recurred it was between the 16th and 19th days, but this may well have been due to chance.

Cases 7 and 11 were instances of pneumococcal infection giving thin pus in which the agglutination of the cocci slowed the presence of antibody. These patients had few toxic symptoms. In Case 8 the cocci were present in enormous numbers, unagglutinated and within intact capsules, and the patient was desperately ill. The fact that there was a recurrence in Case 11 suggests that the presence of antibody, beneficial in other respects, may not affect the period necessary for permanent sterilization of the cavity.

Case 10 shows the loculation which often occurs in pneumococcal cases (Figs. 7 and 8). There was an antero-medial pocket, the pus from which became sterile on the 14th day, whereas that from the postero-lateral pocket did not become sterile until the 20th day.

Of special interest was Case 6, that of a young woman aged 28 who developed a tuberculous pyopneumothorax after haemorrhage during the division of adhesions. This became secondarily infected with an *anaerobic streptococcus*. The organism was killed after administration of 155,000 units of penicillin, and the patient became afebrile and was able to go to a sanatorium.

TABLE II.—12 Uncomplicated Cases

Case	Bacteria	Continuous Penicillin Treatment	Sterile	Cocci all Abnormally Small	Recurrence	Antibody
4	Haem. strep.	39 days	2 days	10 days	—	Present
5	"	10 "	2 "	8 "	16th day	
7	Pneumococcus	9 "	1 "	2 "	—	
3	"	8 "	3 "	1 "	—

15	Non-haem. strep.	9 "	9 "	9 "	19th day	
16	"	6 "	2 "	4 "	18th day	
18	Haem. strep.	14 "	1 "	12 "	—	

Case 14 was that of an American military policeman who was shot through the chest and developed a traumatic haemothorax. After as much blood as possible was aspirated he was given three

injections of 10,000 units of penicillin on successive days. He made an uneventful recovery.

Discussion

The above cases show that, provided the infecting organism is susceptible, an empyema cavity can be sterilized by repeated aspiration of the pus and injection of penicillin, and that the toxic condition is thereby relieved. This confirms the findings of Keefer and his colleagues (1943), Bennett and Parkes (1944), Christie and Garrod (1944), Dawson and Hobby (1944), Herrell (1944), and Bloomfield and his colleagues (1944).

It is too early to assess the final results of the treatment, since further improvement is expected in some cases, while others may yet develop symptoms arising from pulmonary fibrosis. But it already seems probable that the simple methods employed, though sometimes satisfactory, especially in elderly patients such as Cases 2 and 3, are at other times insufficient. The persistence of a purulent effusion is undesirable if pleural thickening and fibrosis of the lung are to be minimized. In our series the period required for final sterilization of the cavity was unpredictable, since Cases 2, 5, 11, and 15 showed recurrence after 8 to 10 days of continuous treatment, whereas Case 3 remained sterile after only 5 days' treatment. Recurrence was found to be easily controlled by a second course of penicillin.

After sterilization there was the tendency for sterile pus to be formed in which minute Gram-positive cocci persisted; and it seems possible that these organisms, although dead, may remain pyogenic. The source of these organisms and of normal cocci in cases of recurrence is probably to be found in the masses of fibrinous exudate lining the walls of the cavity, the removal of which might be expected to hasten sterilization and limit the formation of pus. For this reason Pilcher (1944) advocates washing out the cavity with sterile saline through a rubber catheter until the returned fluid is clear, before injecting penicillin, whereas Tubbs recommends rib-resection and removal of the fibrinous masses lining the cavity as soon as the infection is under control and the patient fit for the operation. There is little hope of avoiding a thickened pleura and rigid chest wall without removal of the fibrinous masses, and it seems reasonable to believe that this can be achieved only after a rib-resection. The removal of this fibrinous material will also help to avoid recurrence of the empyema in such cases at a later date. The presence of grave toxæmia indicates a lack of specific immunity and the probability of underlying pneumonia. General treatment is clearly desirable, but sulphonamides, except in the case of a resistant organism, might usually be found as satisfactory as penicillin. The use of type-specific antipneumococcal serum, if available, might also hasten the restoration of the lung in these cases. Breathing exercises will encourage re-expansion of the lung in the convalescent stage.

In secondarily infected tuberculous pyopneumothorax the ability to remove the invading organism will constitute a great advance and will entirely alter the prognosis of this serious complication of pulmonary tuberculosis.

Tudor Edwards (1943) has shown that the incidence of infection in traumatic hæemothorax caused by penetrating wounds is 21.9%, and by non-penetrating ones it is 11.3%. Our one case was caused by a penetrating wound, and infection did not occur. It seems justifiable to hope that penicillin will play a decisive part in preventing infection in these cases.

Summary

A report is given on 17 cases of empyema treated with penicillin. In 10 the invading organism was the streptococcus and in 7 the pneumococcus.

Penicillin will normally sterilize the pleural cavity, provided that the infecting organism is penicillin-sensitive. Aspiration alone, however, often leaves a thickened pleura and a rigid chest wall, with the consequent disabilities of reduced vital capacity, fibrosis, and risk of recurrent pulmonary infection. Rib-resection is frequently necessary to remove the masses of fibrin which collect in the cavity and thus avoid these complications.

One case was a secondarily infected tuberculous pyopneumothorax in which the invading streptococcus was killed by penicillin.

One traumatic hæemothorax with a penetrating wound was successfully treated with penicillin to prevent infection.

We are indebted to Prof. R. V. Christie and to the Committee on Clinical Trials of Penicillin of the Medical Research Council for the supplies of penicillin.

PENICILLIN IN OPHTHALMOLOGY

BY

J. G. MILNER, F.R.C.S.

Squad. Ldr., R.A.F.V.R.

This report comprises a series of cases investigated by different observers: Series I, by Squad. Ldr. Sampson, R.A.F.V.R.; Series II, by Squad. Ldr. Burr, R.A.F.V.R. (and others); Series III, by Squad. Ldr. Palin, R.A.F.V.R. (and others); Series IV, by Squad. Ldr. Milner, R.A.F.V.R. In compiling the report I have tabulated the several results separately, with the comments of the various observers. Finally a brief summary of the results as a whole is given. A comprehensive analysis was made possible by ensuring that all observers used the same source of supply of penicillin. Dosage and method of treatment were the same at the different hospitals. The cases were treated between mid-December, 1943, and the end of March, 1944.

Preliminary

1. *Strength and Dosage.*—The drug was used (1) as drops, 500 Oxford units per c.cm.; (2) as ointment, 100 Oxford units per gramme—made up in lanette wax and vaseline. Dosage was uniform so far as was possible. Three drops were instilled into the conjunctival sac three times a day, making a daily dosage of 250 units. Ointment was used in blepharitis and acute conjunctivitis, the daily dosage being approximately 30 units. The only other treatment employed was a preliminary irrigation with normal saline; 1% atropine drops were also used where indicated.

2. *Local Reaction.*—About 50% of the patients complained of smarting after the application of drops; this soon dispersed. The majority of those having ointment stated that it was more irritant than drops, the effect lasting about 10 minutes.

3. *Activity of Penicillin.*—Some experiments were carried out for me by Squad. Ldr. Leslie, R.A.F.V.R., to determine how long penicillin remained potent in the conjunctival sac. Two assessments were made on the same patient, using the same eye, an interval of several days elapsing between the experiments.

A. Two drops of penicillin (500 units per c.cm.) were instilled into the conjunctival sac at 9 a.m. Specimens of conjunctival secretion were taken at hourly intervals and estimated for their inhibitory effect against constant amounts of a known dilution of an 18-hour broth culture of a penicillin-sensitive staphylococcus. The following technique was used: (i) Specially prepared pipettes calibrated to deliver 10-c.mm. drops. (ii) 1 drop (10 c.mm.) of conjunctival secretion was added to 1 drop (10 c.mm.) of sterile human serum and thoroughly mixed with one loopful (approximately 0.5 c.mm.) of a 1/1000 dilution of an 18-hour broth culture of a standard staphylococcus provided by the Central Laboratory at Halton (Oxford strain 1). The admixture was carried out on a sterile slide and the mixture covered with a sterile cover-slip and sealed with molten paraffin wax. The "cells" thus prepared were incubated at 37° C. for 24 hours. (iii) The control cell was set up. This consisted of two 10-c.mm. drops of sterile human serum plus a loopful of the staphylococcus suspension treated in the same way as the other cells. (iv) A second control, consisting of two 10-c.mm. drops of normal conjunctival secretion, was used, to which was added a loopful of staphylococcus suspension treated, as above. This produced a good growth of colonies.

Result.—The growth of staphylococci was completely inhibited in the first 4 cells. There was no inhibition in the 5th-hour specimen as compared with the control, which yielded a good growth of discrete colonies.

B. This experiment was conducted in exactly the same way as A, with the following modifications: (i) Penicillin ointment (100 units

per gramme) was used instead of drops. (ii) The same penicillin-sensitive staphylococcus was employed as in A, but a 1/500 dilution of an 18-hour broth culture was substituted for the 1/1000 dilution used in experiment A.

Result.—The growth of the staphylococcus was completely inhibited in the first 5 cells—i.e., 5 hours. The 6th-hour cell showed partial inhibition of a fairly high degree (there were 3 colonies in this cell, as compared with 27 in the control cell). A standard loopful of the staphylococcus dilution subcultured on a blood-agar plate and incubated at 37° C. for 24 hours yielded 33 colonies.

From these experiments it is clear that penicillin drops are potent for 4 hours and ointment for 6 hours. Frequency of treatment can be regulated accordingly.

4. Type of Case Treated.—Blepharitis, styes, dacryocystitis, conjunctivitis, infective corneal ulceration, and infective chalazions are obvious choices. Besides these, penicillin was tried in episcleritis, trachoma, disciform keratitis, dendritic and marginal ulcer, and mild conjunctival hyperaemia (such as is associated with allergy, reflex irritation, sensitive skin, or seborrhoea, etc.). In my own clinic it is used as a routine in all eye injuries and all cases of facial burns in which the eyes are involved.

5. Culture.—A preliminary culture was taken from the conjunctival sac. The culture was repeated after 48 hours and if still positive was again repeated when the case was clinically better. The technique of culturing varies; the one employed in my series was advocated by Squad. Ldr. O'Connor, R.A.F.V.R., who did this part of the work for me. The culture was sown in nutrient broth (24 hours) and then resown on blood agar (24 hours). Too much reliance is not to be placed upon the results of conjunctival culture, and in estimating results the clinical picture was considered more important.

Series I. Squad. Ldr. Sampson. Total Cases, 21

1. Blepharitis.—3 cases. All chronic, of many years' standing. Two showed *Staph. aureus* on culture; one was sterile at the end of treatment, which lasted 11, 7, and 10 days respectively. No recurrence for 2 months.

2. Acute Conjunctivitis.—5 cases (early, uncomplicated). Average duration of treatment, 4½ days. The only organisms isolated were diphtheroids.

3. Chronic and Recurrent Conjunctivitis.—6 cases. Two were associated with seborrhoeic dermatitis, one with dacryocystitis. Average length of treatment, 8 days. 1 case unimproved by penicillin after 11 days and growing *Staph. aureus* was cured by sulphacetamide (albicid) in 3 more days.

4. Phlyctenular Conjunctivitis.—1 case. Cleared after 4 days. 7 weeks later there was a recurrence, which cleared after 3 days.

5. Corneal Ulcer.—3 cases. One showed no improvement after 4 days (no atropine). One cleared in 7 more days with atropine. The second ulcer failed to respond to 4 days of penicillin, but cleared after 5 days of sulphacetamide. (This was a case of rosacea, and recovery was considered not to be due to treatment.) Case 3 failed with sulphacetamide but cleared after 5 days of penicillin.

6. Conjunctivitis of Socket.—1 case. Complete cure after 10 days.

7. Herpes Ophthalmicus.—1 case. Recovery not accelerated by 15 days of treatment.

8. Acute Meibomitis.—1 case. 10 days' treatment, with clinical

Squad. Ldr. Sampson's Comments.—(a) Blepharitis: Cases did better than they would with other forms of treatment. (b) Acute conjunctivitis: Penicillin is no improvement upon sulphacetamide. (c) Conjunctivitis of socket: An improvement upon other forms of treatment. (d) Herpes ophthalmicus: No improvement. He considers that the only condition which definitely does better with penicillin than other forms of treatment is blepharitis; otherwise sulphacetamide is as good.

Series II. Squad. Ldr. Burr (and Others). Total Cases, 26

1. Blepharoconjunctivitis.—7 Cases, All Bilateral

Culture	Days under Treatment	Result
(1) Sterile	8	Nearly normal
(2) Rt., sterile .. .	9	Not improved
Lt., haemophilus
(3) Sterile	5	Improved
(4) Rt., <i>Staph. albus</i> ..	12	Normal
Lt., sterile
(5) Rt., non-haem. strep. ..	18	Improved
Lt., staphylococcus
(6) Rt., streptococcus ..	11	Improved
Lt.,
(7) Sterile	2	No result

2. Conjunctivitis, Acute.—5 cases. Three cases with positive culture were treated for 10, 8, and 11 days. The first two were cured; the third (*Staph. albus*) grew worse in spite of treatment. Two other cases were sterile and were treated hourly. They were improved after 4 and 5 days respectively.

3. Conjunctivitis, Phlyctenular.—4 cases. Three were cured (11, 7, 9 days); 1 not improved (13 days).

4. Corneal Ulcer.—5 cases. Two grew *Staph. albus*; one unimproved in 3 days, the other healed in 7 days. Three other cases were sterile, and healed in 6, 9, and 2 days.

5. Corneal Abrasion.—1 case. Still some conjunctivitis after 5 days.

6. Infected Socket.—2 cases (sterile). Improved after 5 and 6 days.

Comments upon this series were not obtained, the work having been carried out by different observers owing to hospital changes.

Series III. Squad. Ldr. Palin (and Others). Total Cases, 40

Owing to a change over of medical officers a detailed report is not available. The following table is a summary:

Condition	Average Response	Relapse Incidence
1. Conjunctivitis	Acute Very good	Nil
	Chronic Good	Ratio 1:6
2. Blepharitis	Subacute Very good	" 1:6
	Chronic Good	" 1:4
3. Corneal ulcer	Infective Good	" 1:5
	Traumatic Very good	Nil
	Superficial Indefinite	Ratio 1:6
4. Keratitis ..	punctate Poor	?
	Other forms Fair	?
5. Impetigo of lids	Good	Nil
6. Dacryocystitis	Good	Nil

Squad. Ldr. Palin's Comments.—The majority of cases treated were: (a) acute conjunctivitis; (b) chronic conjunctivitis; (c) chronic blepharitis. Results in Group a were truly dramatic, complete subjective and objective cure being achieved in 6 cases within 24 to 48 hours; in these cases the organisms were pneumococcus and/or *Staph. aureus*. In Group c some of the "chronics" were themselves amazed at finding a degree of improvement they had not experienced in years of different treatments. One case of dacryocystitis demands special mention. After dacryocystorhinostomy the wound did not heal, and 10 days after operation was still gaping and discharging pus (with fistula formation). Treatment with penicillin was instituted, and within 72 hours the wound edges were completely and cleanly united and the fistula closed.

Series IV. Squad. Ldr. Milner. Total Cases, 57

A. Blepharitis. 16 Cases. Approximate Dosage, 280 Units a Day

Type	Culture	Culture Sterile (Clinically Clear in Days)	Total Dose (Units)
1. Recurrent ulcerative	<i>S. aureus</i>	5	1,400
2. Unilateral ulcerative	"	7	1,960

8 Dendritic	Sterile	Not improved after 5 days	1250
9 Marginal	Sterile	Some improvement after 4 days	1000
10 Disciform keratitis	Sterile	Not improved after 4 days	1000

Comment on Group 4—All cases showed great improvement after treatment with penicillin. Cases 12 and 13 had had chronic blepharitis for years, Case 13 was particularly bad, with brittle misplaced lashes (though no trichiasis). After three days both these patients were emphatic that their eyes had not been so comfortable for years.

Comment on Group B—Acute conjunctivitis has been uncommon in my Service experience of four years, when it occurs it is usually of the catarrhal variety, and purulent or mucopurulent conjunctivitis is very uncommon. Thus I have not had the opportunity of using penicillin in bad cases. In catarrhal or mildly mucopurulent cases with a positive culture it undoubtedly is effective. Where the culture is sterile I doubt if it is more effective than other methods of treatment. The advantage of its use in such cases would be to maintain the sterility of the conjunctival sac while healing and recovery were taking place. In chronic conjunctivitis, unless definitely due to a low grade infection, I doubt the efficacy of penicillin. So many chronic conjunctivitis cases have a very obscure aetiology I associate many of them with reflex irritation, allergy, metabolic derangements, skin disorders, etc.—in which the condition is more a hyperaemia than an inflammation—and in these cases there was no response to penicillin, as would be expected. In cases of burns penicillin is of very great value. Conjunctivitis occurs in facial burns, and as the lids begin to

contract into ectropion the conjunctivitis gets worse in spite of treatment and exposure keratitis is almost a certainty. The eye is usually too irritable for a contact lens and the lid margins too friable (or the pull of the ectropion too great) for tarsorrhaphy to be successful. By keeping the conjunctival sac sterile with penicillin the eye can be protected from infective sloughing ulcers until the case is ready for plastic repair. Case B 8 and Case C 4 are examples. I am quite sure that but for penicillin one eye would have been lost or so severely damaged by corneal involvement as to be useless in each of these cases. All burns which even remotely involve the eye now have routine penicillin treatment—250 units a day in each eye.

Comment on Group C—The only infective type of ulcer in this series was Case 4, which has been referred to above (NB—I have seen only 4 cases of severe corneal ulceration during 4 years at an R.A.F. hospital). Penicillin would seem to be of little value in herpetic keratitis or marginal ulceration.

D Dacryocystitis (Chronic)—One case profuse growth of *Staph. aureus* and Koch-Weeks bacillus. Sterile in 8 days. Approximate dose 2000 units. In this case penicillin was injected into the sac, which was afterwards successfully operated upon.

E Trachoma (Old)—One case *Staph. aureus*—1 day—1000 units. This was a case of old trachoma, and it seemed to be a secondary infection with no active disease. This contention proved correct as the eye cleared up rapidly under penicillin.

F Episclelitis—One case Sterile—4 days—1,000 units. This case had recurrent episclelitis in one eye and had already been treated by me twice for severe recurrences. On the third occasion penicillin was tried for experimental purposes, and the nodules disappeared very rapidly. This has happened on a second occasion. It seems here again by keeping the conjunctival sac sterile, penicillin aids the eye to heal more rapidly.

G Folliculosis—One case Sterile—no improvement in three days—750 units.

H Injuries—Penicillin is used as a routine in all cases of corneal foreign bodies and abrasions. Three perforating injuries have been seen during the period covered by this report, but in all cases the damage was extensive and the eye had to be removed. I have not yet had the opportunity of using the drug in conjunction with an intraocular operation or penetrating injury where the eye could be saved.

Summary

I Dosage—In the strength used by us (drops, 500 units per c.c.m., ointment, 100 units per gramme) penicillin would appear to retain its potency for 4 hours (drops) and 6 hours (ointment). Frequency of treatment can thus be regulated according to the requirements of the case. Very frequent applications of penicillin would seem unnecessary.

2 Indications for Use—All observers are agreed that penicillin affords the best results in blepharitis, most of us would add acute conjunctivitis, but I have already indicated the small number of cases of acute infective conjunctivitis that occur under Service conditions—at least, in my experience. I do believe that in civilian practice, particularly in the hospital out-patient departments, penicillin will be the treatment of choice in these cases. The same remarks apply to corneal ulcers (infective). In chronic dacryocystitis I believe also it will become habitual to use penicillin preliminary to operation, but the cases seen have been too few for further comment. Recurrent styes and infected chalazion seem to be limited by applying penicillin, particularly in the intervals between recurrences.

As certain indications for penicillin I would add to the above (1) all cases of serious injury to the eye, whether penetrating or not (2) all cases of facial burns involving the eye, (3) routine post-operative treatment.

It is impossible to assess the value of the drug in cases of injury, because there is no control for comparison. I have not yet had sufficient cases of penetrating injury to conclude whether the incidence of sepsis is less than before penicillin was employed. This is a matter requiring further investigation. Nor have I any evidence that non-infected cases heal more quickly with penicillin. Nevertheless I would advocate its use.

There remain a large assortment of cases in which penicillin has been used with doubtful or conflicting results. Chronic conjunctivitis seems to respond slightly, and the consensus of opinion is, I think, that penicillin is not of much value. Here I would repeat what I have mentioned above—that where a secondary infection with a penicillin sensitive organism is also present, by inhibiting the growth of such an organism the drug may indirectly aid and accelerate healing. This statement applies to many inflammations which are, *per se*, unaffected by penicillin—such as episclelitis, trachoma, phlyctenular keratitis, marginal ulceration, herpetic keratitis, and many others.

Two observers in this series have been struck by the benefit obtained with penicillin in cases of infected socket. I have been impressed, in a series of 6 cases (seen outside the date range of the report), by the inefficacy of the drug. I found after some experimentation that 2½ red prontosil was much more effective. There are therefore some types of ocular inflammation which require much more extensive investigation before we can be sure how much to expect from the use of penicillin.

With regard to recurrence of inflammation I can say little yet. Because cases of one's own have not returned does not mean that there have been no recurrences; the patients may have gone to another part of the country. My opinion is that penicillin, being bacteriostatic and not bactericidal, will have little power to prevent recurrences unless it can be used, more or less as a routine, in intervals between exacerbations.

Finally, it must be remembered that many ocular inflammations are secondary to, or at least run parallel with, other affections—e.g., blepharitis and seborrhoeic dermatitis, conjunctivitis and rosacea, etc. The treatment of the underlying condition must not be lost sight of in the enthusiasm of employing a new method.

Synopsis of Indications

Definite	(a) Blepharitis	Acute and chronic Infective
	(b) Acute conjunctivitis	
	(c) Corneal ulcer	Recurrent Prophylaxis
	(d) Dacryocystitis	
	(e) Styes, chalazion	"
	(f) All ocular injuries	
Doubtful	(g) Facial burns	"
	(h) Immediate post-operative	
	(a) Chronic conjunctivitis	"
	(b) Infected socket	
	(c) Other external inflammations, with a possible secondary infection	

I believe penicillin to be quite useless in cases of deep keratitis, iritis, or cyclitis.

In conclusion I should like to emphasize the desirability of those concerned ensuring that all cases of facial burns with ocular involvement be given penicillin from the very beginning of treatment. In such a way I believe a number of ulcers from exposure keratitis can be avoided.

My thanks are due to Air Cdre. P. C. Livingston for making possible the supply of penicillin; to Squad. Ldrs. Sampson, Burr, and Palin for their co-operation, and for supplying me with their reports; to Squad. Ldr. R. J. O'Connor for the bacteriological culture work; to Squad. Ldr. W. I. Leslie for conducting experiments upon the time potency of penicillin; and to Sister M. C. E. Lodge for carrying out exact lines of treatment in my series of cases, thus ensuring uniformity of results.

PENICILLIN AND SULPHONAMIDES IN INFANTILE GASTRO-ENTERITIS

BY

ELIZABETH BURNS, M.B., B.Ch., D.C.H.

AND

W. GUNN, M.B., F.R.C.P.

(North-Western Fever Hospital, L.C.C.)

The high incidence of acute gastro-enteritis in infants (familiarily known as D. and V.) continues to give cause for anxiety, showing a definite upward trend on the evidence of the figures of deaths from enteritis and diarrhoeal diseases in those under 2 years, which in England and Wales for 1939 to 1943 were: 2,812, 2,891, 2,985, 3,415, and 3,518 respectively. A disease predominantly of the hot months (hence the name summer diarrhoea) in the period before the first world war, it now shows no particular seasonal predilection except a tendency to increased severity and perhaps also increased prevalence during the period when catarrhal colds are rife, in the late winter and early spring months. In the absence of general notification (which should be made compulsory and be limited to the first year of life) estimates of the real incidence can only be conjectural, while mortality figures tend to be vitiated by inaccurate or incomplete certification, as exact diagnosis is not always easy in the absence of definite knowledge of the essential aetiology. Despite arguments to the contrary, there are no valid grounds for considering this disease to be different from so-called neo-

natal diarrhoea, except for such differences as are attributable to the physiological characteristics of young babies. Workers in this field have recently inclined to the view that invasion of the upper respiratory tract, due most probably to a virus or group of viruses, is the primary cause, and the damage to the mucous membranes thereby sustained renders them more vulnerable to the ordinary bacterial flora of that region; whether the virulence of organisms harboured before attack may be enhanced in the process has not been definitely established. A somewhat similar process may occur in respect of the normal intestinal bacteria, notably coliforms and enterococci; nor should it be forgotten that the same primary organism (causing identical disease processes so far as can be determined clinically) may gain entry by either the gastrointestinal or the upper respiratory tract, as has been proved in poliomyelitis.

The five recent cases described here, though representative, naturally belong to the severer form of the disease, which may range from the mildest grades, in which evidence of toxic-infective processes may be minimal or absent, to fulminating attacks. It is a matter of experience that the latter may sometimes respond to treatment more swiftly and completely than certain intermediate grades, the crucial difference apparently being the presence or absence of an infective focus and the success or failure of the measures employed to eradicate or neutralize it. All five cases were treated in single-bedded rooms (technically termed cells and often erroneously referred to as cubicles) in the same isolation unit and attended by the same medical and nursing staffs, with strict observance of aseptic nursing technique, including the wearing of "Cestra" type masks.

Management of Cases

To avoid unnecessary repetition, an outline of the management of the cases is given at this stage. A complete history of the patient from birth and the recent history of immediate contacts are followed by weighing of the patient and restoration measures such as warmth and fluids by mouth; if dehydration is present an intravenous infusion of Hartmann's solution is given supplemented by 5% glucose at once or after a few hours, and by 4 parts solution to 1 part serum or plasma (the latter occasionally causes febrile reactions which may mislead) according to severity of symptoms and duration of disease, until metabolism is restored to normal as checked by level of plasma bicarbonate, proteins, urea, and chlorides, and by blood transfusion as shown by haematocrit readings and blood-count determinations. With experience these examinations may often be dispensed with, but avoidance of anaemia and oedema is best secured by periodic tests. The duration of the drip may vary from 1 to 5 days—average 3 days. Swabs of throat, nose, and nasopharynx (the most important site of the three) and specimens of faeces and urine are taken on admission and repeated as considered necessary. If vomiting persists only sips of Hartmann's solution or boiled water are given; but if it has ceased, increasing quantities are taken orally, deducting the amount from the drip intake. In 24 to 72 hours feeding is resumed, starting usually with a 1 in 4 dilution of a feed suitable for the age, rapidly reaching full strength according to appetite and tolerance: some infants can take only a 1 in 8 solution, while others can stand a 1 in 2 or even full-strength mixture from the outset, the remainder of fluid being given between feeds if the prescribed volume based on body weight is refused at the usual feeding-times. If there is no contra-indication the food given before attack is chosen; if it was thought to disagree with the patient humanized national dried milk is the food of choice, and rarely requires modification such as citrated, peptonized, or acidified milk. Occasionally "Secway" may be needed to bridge the period between fluids and feeds. Difficulty at this stage is nearly always attributable to an infective focus, usually in the middle ear, occasionally in the renal pelves; and a sulphonamide, commonly sulphamezathine or sulphathiazole, is given either in the drip or orally with a view to preventing or even to securing resolution of the inflammatory process. Success is conditioned by the susceptibility of the causative organism, the natural resistance of the patient (specific immunity may likewise be a factor), and the nature and timing of such operative procedures as are adopted. Proper timing is considered of vital importance, as

harm may be caused by premature operation as positively as by inadequate or tardy intervention.

The essential data, with critical comments, are given for each case in chronological order.

Case I

W. G.; 5/12 M., weight 15 lb. 4 oz., artificially fed. May 21, 1944: Onset—stools relaxed and green. Admitted 4th day; T. 100.6° F. Moderate dehydration present; intravenous Hartmann's solution on following day with plasma later, and next day bilateral myringotomy, revealing sero-sanguineous exudate; bilateral cortical mastoidectomy 12 hours later; mucous membrane of the mastoid cells was inflamed and bone soft and red; no definite pus found. Wounds were stitched, leaving fine drainage-tube at lowest part for introduction of dilute penicillin (400 units per c.cm.) every 6 hours for 5 days; complete healing followed in 9 days. Throat and nasopharynx—*Staph. aureus*, *M. catarrhalis*, and coliforms; nose—*Staph. aureus*; right ear—*M. catarrhalis*, *Staph. albus*; left ear—no growth; mastoid bone—no growth.

Treatment.—Sulphathiazole 6 g. in 4 days on admission, and sulphamezathine 12 g. in 7 days, starting 5 days later. The patient did not improve—fever, diarrhoea, and loss of weight persisting despite four drips (three intravenous, one tibial marrow) and one blood transfusion (raising haemoglobin from 62 to 84%). A trace of protein, some pus cells and red cells, and *Staph. aureus* and enterococci appeared in the urine at this stage (catheter specimen). Reopening the mastoids was considered unwarranted. Blood culture taken shortly before death on the 27th day of the disease revealed numerous *Staph. aureus*, partially sensitive to sulphonamides.

Necropsy.—Left mastoid—mucoid material; right—frank pus present, bone soft; from both, *Staph. aureus* and coliforms were isolated. Right middle cerebral vein thrombosed with purulent exudate along course.

Comment.—Both myringotomy and mastoidectomy were probably undertaken too early; a more generous and longer course of sulphonamides advisable; mastoids might have been reopened with benefit. Coexisting renal damage may mislead, but appearance of pathogens in urine should suggest taking a blood culture.

Case II

B. W.; 6/12 M., weight 14 lb. 15 oz., artificially fed. May 24, 1944: Onset with fever, loose green stools, and bronchitis, for which sulphamezathine 9 g. in 4 days was given. A week later vomiting and continued diarrhoea led to dehydration; corrected by intravenous Hartmann's solution with glucose and plasma for 5 days and a second course of sulphamezathine 15 g. in 5 days, of which 6 g. was by the intravenous route; protein (a trace), scanty pus cells, and coliforms appeared in urine in the course of this treatment. Three weeks after onset bilateral myringotomy revealed muco-pus on both sides, containing *Staph. aureus*. No improvement followed, and cortical mastoidectomy was performed next day; the bone was softened and muco-pus was present in the mastoid cells, but cultures taken at operation proved negative. Fever continued, and blood culture taken 4 days after operation was found to grow penicillin-sensitive *Staph. aureus* scantily. Penicillin 40,000 units every 24 hours was given by intravenous drip for 6 days and 5,000 units 3-hourly for an additional 2 days, when fever had just gradually subsided to normal. Blood culture was sterile on the day after starting penicillin therapy, which was continued to prevent relapse. As the penicillin-tube opening was still patent 13 days after operation and discharged mucopurulent material, reopening of the right mastoid was considered, but was deferred until rise of temperature or other sign of inflammation indicated; but subsequent recovery was rapid and uneventful.

Comment.—The negative bacteriological findings are possibly due to sulphonamide present in the swab material, para-aminobenzoic acid not being added to the culture media. The presence of renal complications did not seem to influence the course of the disease. Timely blood culture and use of penicillin saved the patient.

Case III

M. P.; 5/12 F., weight 11 lb. 11 oz., artificially fed. May 24, 1944: Admitted with history of watery, green, offensive stools for 6 days, preceded by cough and nasal discharge; mild dehydration; T. 98.6° F. The upper respiratory tract revealed nothing noteworthy apart from *Str. viridans* in the nasopharynx; urine normal. Some improvement followed a course of sulphamezathine, but 10 days later fever recurred with diarrhoea and pronounced dehydration, requiring an intravenous drip with plasma. Bilateral myringotomy 2 days afterwards yielded watery exudate containing *Staph. albus* and coliforms on the right side and blood only (sterile) on the left side. No improvement ensued, and a plasma drip followed by blood transfusion (haemoglobin raised from 75 to 95%) was needed to sustain life. A second bilateral myringotomy gave a dry result, but mastoidectomy 4 days later revealed frank pus and necrosed bone (left) and soft readily bleeding bone (right), both

sterile on culture. The blood was also sterile. With local penicillin healing of the wounds took place in 10 days. Some fever continued for 5 days after operation, but thereafter gain of weight and general progress were satisfactory.

Comment.—The negative bacteriological findings may have been due to sulphonamide either in the tissues killing the organism or on the swab inhibiting growth. Efficacy of mastoidectomy difficult to assess in such cases, although subsidence of fever is suggestive.

Case IV

P. L.; 8/12 F., weight 11 lb. 11½ oz., artificially fed. June 10, 1944: Onset sudden, with copious vomiting and loose, yellow, offensive stools; moderate dehydration; temperature 99.6° F. On admission bilateral myringotomy: left, sero-pus; right, blood only; both yielding *Staph. albus*. Upper respiratory tract revealed nothing of note apart from pneumococci in nasopharynx. Fever subsided for 3 days, when it recurred, necessitating an intravenous drip with plasma and 3 days later 100 c.cm. blood, raising haemoglobin from 73 to 98%. The urine was found to contain protein, numerous epithelial and pus cells, and scanty red cells; *B. coli* and *proteus* were found on culture. Blood culture was sterile. Fever and symptoms subsided in 3 days on a course of sulphathiazole, 10 g. in 6 days, and remained settled. A month later the urine still contained *B. coli* on culture, and a trace of albumin; otherwise recovery appeared to be complete.

Comment.—Pyelitis seemed to be the sole cause of the gastro-enteritis, responding rapidly to sulphonamide, but it may be merely a complication.

Case V

R. B.; 2/12 M., weight 6 lb. 9 oz., breast-fed for first 3 weeks. June 23, 1944: Cough and diarrhoea; general condition satisfactory. Admitted a week later with vomiting and frequent green, watery motions but without gross dehydration. Next day condition worse, requiring an intravenous drip. Throat and nose yielded *Str. viridans*, *M. catarrhalis*, and coliforms; nasopharynx—*Staph. aureus* and pneumococci; urine—trace protein, epithelial cells, *B. coli*, and *proteus*. Two days later myringotomy revealed a small amount of mucooid pus (right) and serous fluid (left), both containing *Staph. aureus* and *albus*, pneumococci, and coliforms. As high fever continued sulphamezathine 9 g. in 4 days was given, and re-myringotomy was done 5 days later, again yielding small amounts of muco-pus and the same bacteria as before. Blood culture next day gave pneumococci Type 8 in uncountable numbers, sensitive completely to penicillin and partially to sulphonamide. Penicillin therapy, 5,000 units 3-hourly intramuscularly, was started, giving a level next day of $\pm 1-8$ after 3 hours, and the dosage was reduced to 4-hourly intervals. The patient seemed better and took feeds readily, but 2 days later a generalized convulsion and meningitic signs appeared; lumbar puncture showed purulent fluid containing numerous pneumococci on culture. No response followed 3 injections of 5,000 units of penicillin given intrathecally at 8-hour intervals, and the patient died 24 hours later.

Necropsy.—Inspissated pus in both middle ears and mastoid cells. Greenish-yellow pus over entire surface of the brain, with subarachnoid haemorrhage over the base.

Comment.—Sulphonamide was given too late in the disease to be effective; blood culture and lumbar puncture undertaken too late; penicillin probably sterilized the blood (a second culture was not taken, as the physical state was poor) but failed to prevent spread to the meninges, which very likely had taken place some hours or days before the convulsion which led to lumbar puncture.

Discussion

The cases recorded above illustrate well the difficulties encountered in locating the infective focus as well as in deciding the measures best calculated to eradicate it and the appropriate time to apply them. Although a history of cough or other symptom of respiratory infection was present in three cases the clinical evidence of such infection was negligible. While pyelitis occasionally appears to be solely responsible for gastro-enteritis, renal infection indistinguishable from mild pyelitis may occur at any stage of an attack, due primarily to upper respiratory infection, and should suggest the existence of bacteraemia or septicaemia originating in mastoid suppuration. All three mastoidectomies were carried out under local anaesthesia, using 1% novcain preceded by 1/4 gr. secenal. With careful infiltration pain is absent or minimal; usually the patients suck their bottles contentedly during the operation. It seems warranted to conclude that, provided other possible causes are excluded, no patient suffering from gastro-enteritis should be permitted to die without operation; if properly prepared for it with intravenous fluids, preferably including human serum or plasma, untoward effects are rare, and benefit some-

times appears to accrue in cases in which evidence of mastoiditis was equivocal at the time of operation. The necessity for operation is governed by persistence of fever, diarrhoea, and/or vomiting and loss of weight despite every effort at resuscitation; the appearance under observation of enlarged posterior cervical glands gives support to the diagnosis, but neither their presence nor their absence should influence the final decision to operate.

There is general agreement that sulphonamides often fail to prevent the onset of mastoiditis and may actually be dangerous in masking the disease. Whether penicillin will succeed where sulphonamides have failed has not been adequately explored, but the present limited experience furnishes grounds for the hope that timely use of the drug will reduce appreciably the high case-fatality of infantile gastro-enteritis.

Summary

Five cases of severe acute gastro-enteritis in infancy, with two deaths, are described; in three patients mastoidectomy was performed, resulting in (a) rapid resolution of suppurative processes found to be sterile at operation; (b) recovery from staphylococcal septicaemia cured by penicillin; (c) death from staphylococcal septicaemia uninfluenced by sulphonamides. Of the remaining two cases one patient with *B. coli* pyelitis improved rapidly with sulphathiazole while the other died from pneumococcal meningitis and septicaemia, not responding to sulphonamide or penicillin therapy.

Our grateful thanks are due to Dr. R. Cruickshank, who carried out the bacteriological examinations, and to Miss Winifred Hall, who undertook the otological work.

A SEVERE HAEMOLYTIC TRANSFUSION REACTION DUE TO THE Rh FACTOR

BY

A. BECK, M.D., Frankfurt, L.R.C.P.&S.

Pathologist, Public Health Laboratory, Burnley

C. V. HARRISON, M.D.

Department of Pathology, Liverpool University

AND

J. M. OWEN, M.B., Ch.B., D.R.C.O.G.

R.M.O., Bank Hall Maternity Hospital, Burnley

The demonstration of the Rh factor in human blood cells (Landsteiner and Wiener, 1940) has led to the elucidation of many previously unexplained haemolytic reactions following the transfusion of apparently compatible blood. Later workers (Levine *et al.*, 1941; Boorman *et al.*, 1942; Race *et al.*, 1943) have shown that the antibody responsible for the haemolysis may develop in an Rh-negative person either as a result of previous transfusions with Rh-positive blood or, in the case of women, as a result of bearing an Rh-positive foetus. In the latter case the infant usually suffers from haemolytic disease of the newborn. In the present case a severe haemolytic reaction followed the transfusion of Rh-positive blood in a woman who had previously been transfused (probably with Rh-positive blood) and also had borne several Rh-positive children. It is not known which of these two factors was responsible for the production of the antibody.

Case Record

Mrs. A., aged 38, had a history as follows:—1929: Forceps delivery; normal baby, Group A, Rh-positive. 1932: Normal delivery, but retained placenta; baby healthy at birth but died at 5 months; cause unknown. 1936: Normal delivery followed by post-partum haemorrhage. Was given blood transfusion (group not known). Baby healthy; Group O Rh-negative. 1940: Normal delivery. This child, who is Group A, Rh-positive, was said to have been jaundiced for four weeks after birth. 1942: Twins. First infant stillborn owing to hydrocephalus; second infant healthy, Group A, Rh-negative. Labour followed by severe haemorrhage. Two transfusions of Group A blood were given, with an interval of 14 days; both were followed by severe rigors.

In 1944 she was seen when 22 weeks pregnant. Urine and blood pressure were normal. In view of a moderate anaemia (Hb 55%, R.B.C. 3,600,000) it was decided to give her a blood transfusion. One pint of Group A blood was administered. One hour later she started to vomit, her pulse became weak, and she complained of

lumbar pain. Anuria set in and alkali therapy was begun immediately. The following morning she was jaundiced. The daily urinary output for the next six days varied between 1 and 4 oz. The urine was dark red in colour and was loaded with albumin. On the fifth day she complained of severe headache, and the next day some oedema of the legs was noticed. On the eighth day normal diuresis set in and her condition gradually improved. On the thirteenth day she left hospital against advice, but had apparently recovered from her haemolytic reaction. The following day she returned with an incomplete abortion. The placenta had to be removed under general anaesthesia. She collapsed before the operation, but rallied sufficiently for it to be completed. She died four hours later, apparently from shock.

A necropsy was performed 24 hours after death. Apart from signs of shock, the significant findings were those related to the haemolytic transfusion reaction. The liver showed signs of fatty change. The kidneys were enlarged to twice their normal size and showed a pale-grey colour with an indistinct cortical pattern. The spleen was greatly enlarged (580 g.) and firm. The abdominal lymph glands were also enlarged.

Microscopical examination of the kidneys revealed the characteristic lesions of "transfusion kidney" as described by previous workers (De Gowing *et al.*, 1938; De Navasquez, 1940). The organ differed from that in average cases in having numerous focal collections of lymphocytes, macrophages, and eosinophils in both cortex and medulla. Similar changes have, however, been described by Goldring and Graef (1936) and by Ayer and Gauld (1942). The liver showed fatty change and slight degeneration towards the centres of the lobules. The spleen, in addition to siderosis, showed marked proliferation of the histiocytic cells of both the pulp and the Malpighian bodies. The abdominal lymph glands presented a similar picture.

Comment

The patient's blood was examined on the 2nd and 12th days after transfusion. The donor was Group A Rh-positive. The patient was Group A Rh-negative, and on the first examination, two days after transfusion, no agglutinable Rh-positive cells were found, indicating that all the transfused cells had been destroyed. On this occasion Rh antibody was demonstrable in the undiluted serum. On the 12th day the Rh antibody titre had risen from 1/1 to 1/8. The husband was found to be Group A, Rh-positive; the blood groups of the children have already been given.

An interesting problem in this case is which of the various possible factors was responsible for the production of Rh antibody. Of the patient's four surviving children two are known to be Rh-positive. It is stated that one of these—the third—was jaundiced for four weeks after birth, and it is probable that this was due to haemolytic disease of the newborn; the absence of signs of haemolytic disease in the case of the fourth child would be due to its being Rh-negative. It is therefore at least possible that the production of Rh antibody may have been due to repeated pregnancies. The Rh group of the blood given in the earlier three transfusions is not known, but on probabilities it is likely that most, if not all, were Rh-positive. Also, the fact that the second and third were followed by reactions is suggestive. The other interesting feature is the remarkable size and reaction of the spleen. There was no evidence of leukaemia in a blood count done shortly before the last transfusion, and neither the necropsy findings nor the histology indicate reticulosis.

We believe that the reticulo-endothelial hyperplasia in the spleen was the result of stimulation by incompatible transfusions; probably two transfusions in 1942 and certainly one a fortnight before death.

Summary

A case is described of a severe haemolytic reaction following the transfusion of Rh-positive blood into an Rh-negative woman who had borne two Rh-positive children and had previously had three transfusions. It is not known which of these two possible factors gave rise to the Rh antibody.

Medical Memoranda

Treatment of Cerebral Malaria

During recent months certain contributions on malaria have appeared in the *Journal* which have apparently been written by authors with limited experience of this disease. Although these contributions have added little or nothing to existing knowledge, they have in the main been helpful to those who are encountering malaria for the first time. This cannot be said of the article by Surg. Lieut. Sneddon (*Journal*, 1943, 2, 814), reporting a fatal case of cerebral malaria, in which the commentary on treatment is seriously misleading.

DOSEAGE OF QUININE

The author records the administration of intravenous quinine in a dosage of 10 gr. daily, and comments that this dosage was higher than the 5 to 7 gr. daily advocated by Manson-Bahr (1942), leaving the impression with the reader that 10 gr. daily should be adequate for the treatment of cerebral malaria. It may be useful to present in tabular form the recommendations of various authorities on the optimum dosage of quinine in that disease.

Authority	Preparation	Initial Dose		Subsequent Dosage Indicated	
		gr.	Route	Amount (gr.)	Route
Field (1935)	Quinine dihydrochlor.	7½	I.V.	10½; up to total of 30 in 24 hours	I.M.
Manson-Bahr (1940a)	"	10	I.V.	" Free and frequent administration of quinine "	Not stated
Manson-Bahr (1940b)	"	15	I.V.	Not stated	—
Manson-Bahr (1942)	"	5-7	I.V.	5-7 daily	I.V.
Napier (1943)	Quinine dihydrobrom.	10	I.V.	Repeat 10 gr. a few hours later, intravenous therapy may be needed for 2 days	I.V.
Nocht and Mayer (1937)	Quinine dihydrochlor.	7½	I.V.	Not stated	—
Rogers and Megaw (1942)	Quinine dihydrochlor.*	7½-15	I.M.	" "	—
Stitt (1942)	Quinine bismarite	10	I.V.	Not more than 30 in 24 hours	I.V.

* Rogers advocates dihydrobromate.

It will be noted that the recommendations above are far from consistent. Though they may each have given satisfactory results in the particular conditions in which they were used, their diversity makes it difficult for the novice to decide on the correct line of treatment. In general it may be stated that the amount of treatment required will vary in inverse ratio to the amount of immunity possessed by the patient. Thus considerably larger doses of quinine may be required for the majority of Europeans and Americans, who usually possess little or no acquired immunity, than for patients living in endemic areas, who may possess partial immunity.

RECENT RECOMMENDATIONS

Since the outbreak of the present war large numbers of Allied troops with attendant medical services have been deployed in highly malarious areas, providing an unprecedented opportunity for the study of malaria in general and of its neurological complications in particular. The following simple directions have been compiled from the most recent recommendations of the Allied Forces on the treatment of cerebral malaria, and are founded on the experience gained before and during the present war. They are applicable to any case occurring in the adult male.

Drug of choice. Quinine dihydrochloride.

Route. Intravenous.

Rate of injection. Very slow. Maximum speed 1 minute per grain; optimum speed, 2 to 4 minutes per grain, if possible.

Initial dose. 5 to 10 gr.

Dilution. Maximum, 6 gr. in 10 c.cm.

Diluent. Distilled water or normal saline if 10 c.cm. is used. Normal or glucose saline for larger quantities.

Subsequent dosage. 6 gr. 4-6 hourly, not exceeding a total of 30 gr. in 24 hours, or 10 gr. 8-hourly, until recovery from coma occurs and satisfactory oral administration is possible.

Intramuscular mepacrine as an adjuvant to intravenous quinine may give good results in the hands of those familiar with its use. I wish to emphasize the necessity for persevering with intravenous quinine in comatose cases even though the prognosis appears hopeless. This is well illustrated in a case reported by Whitchill (1943). Whitchill's patient was in coma for approximately 34 days, excluding a lucid interval of 1½ days, and, although the coma was complicated by an acute malanial nephritis, recovery ensued after a total dosage of 75 gr. of intravenous quinine had been given.

POINTS FOR COMMENT

There are two other points in Surg. Lieut. Sneddon's article which are worthy of comment:

1. *Use of Intravenous Salines.*—A not infrequent terminal event in cerebral malaria is pulmonary oedema, and caution should always be exercised not to give more intravenous saline than is necessary, and to give it slowly. The administration of fluids through a Ryle's tube passed into the stomach and connected to a drip apparatus has

been recommended by Lieut.-Col. G. A. Ransome, I.A.M.C. (personal communication). It is advisable to nurse patients in a semi-recumbent position rather than dead flat, in order to prevent hypostatic congestion.

2. *Lumbar Puncture.*—This should be carried out as a routine in coma. A certain proportion of cases of cerebral malaria suffer from cerebral oedema with a raised C.S.F. pressure, and, in these, improvement may follow the judicious removal of C.S.F. Further, in malarious areas cases of cerebrospinal meningitis may suffer simultaneously from malaria. The dual pathology may here easily be missed unless a lumbar puncture is carried out.

In conclusion I would like to express my emphatic concurrence in Surg. Lieut. Sneddon's statement that if treatment is to be successful it must be prompt. More than any other factor in the management of the case, the prognosis in cerebral malaria depends upon the speed with which the diagnosis is made and treatment instituted.

Two Cases of Snake-bite

The following cases are recorded for the reason that snake-bite is an uncommon accident in this country and that it must be still more unusual for two patients to be bitten by the same snake. The great difficulty experienced in obtaining antivenene is also a matter for consideration.

CASE HISTORIES

On May 18, 1944, two healthy boys—A. T., aged 12, and J. O., aged 14—were playing on an open heath when A. T. saw and caught hold of what proved to be an English viper (*V. berus*), commonly known as an adder, 24 in. long. The snake bit him and he dropped it, whereupon his companion gave chase and, having grabbed the snake, was also bitten a few minutes later. A. T., who received the first bite at 3.30 p.m., vomited immediately and felt so ill that he lay down on the grass, where he was found 20 minutes later by his schoolmaster, who stated that the boy was very pale and drowsy, was unable to walk, and complained of sore throat, pain in his abdomen and feet, and great thirst. He was vomiting. The bite was on the dorsum of his right hand, which was much swollen, with a dark-blue area surrounding the bite. The master incised the bite with a penknife sterilized in dettol, but very little blood flowed and it clotting immediately.

The boy was admitted to the West Suffolk Hospital, Bury St. Edmunds, at 5.30 p.m., in a condition of extreme shock. His colour was grey-blue, and he was cold, limp, and semi-conscious. Respiration was very shallow and the radial pulse was not palpable. Temperature was subnormal. He complained of thirst and sore throat. His right hand was swollen, shiny, and grey-blue in colour; there was no lymphangitis, but the axillary lymph glands were enlarged and very tender.

Nikethamide (coramine) and adrenaline were administered, and the usual measures for treatment of shock were taken. By 7.45 p.m. his general condition had considerably improved and he was complaining of pain in his hand and abdomen and of sore throat. Examination showed no haemorrhages in his skin or mucous membranes. Pulse 120 and of good volume; heart and lungs normal; abdomen somewhat distended, and tympanitic and tender; deep reflexes present. A puzzling sign was wide dilatation of both pupils with loss of light and accommodation reflexes. It was discovered subsequently that during the morning atropine had been instilled by an ophthalmic surgeon by whom he had been examined.

He was given 12 minims of nupentene, and had a fairly comfortable night. On the 19th his general condition was much improved. The right arm, however, was swollen up to and beyond the elbow and was extremely tender. In the afternoon of that day a supply of antivenene was obtained through the Ministry of Health, but the boy was so much better that administration was withheld. On the 20th he complained more of sore throat and dysphagia, and a hot, red, and very tender oedema involved the whole of his right arm and shoulder and upper part of chest, back and front. 10 c.cm. antivenene was given intramuscularly at midday. On the 21st his general condition was much improved and there was no increase of the oedema. On this and the next day he developed extensive ecchymoses in the skin of his right arm and chest. There were no haemorrhages elsewhere, and his urine showed no red blood corpuscles. Recovery was subsequently uneventful, and he was discharged on May 30. His temperature had never risen above 100°.

The other patient (J. O.) was bitten on the outer side of the little finger of his right hand. Another boy promptly sucked the wound and tied a ligature round his arm. He developed no symptoms until 14 hours later, when he vomited and complained of sore throat and difficulty in speaking. His right hand became swollen and painful.

He was admitted to hospital at 8 p.m. There were no signs of shock, but tender swelling and redness of his right hand, with marked lymphangitis and axillary lymphadenitis. The site was incised under gas anaesthesia and bled freely; a potassium permanganate dressing was applied. No other symptoms developed, and except for slight swelling of his finger he was well on May 22.

COMMENT

It is interesting to note that in this instance the viper did not discharge all its venom at the first bite.

The condition of the boy A. T. on admission was most alarming, and it is clear that antivenene as a life-saving measure would need to be administered within a few hours of the bite. Whether the dose given in this case prevented further oedema and lymphangitis is a matter for speculation. It proved impossible to procure antivenene through the usual channels, and the supply obtained through the good offices of the Ministry of Health was received only after nearly 24 hours' delay. It was prepared by the Pasteur Institute, Algiers, against the venom of the horned viper of Africa (*Cerastes cornutus*). Barrett (Lancet, 1934, 2, 60) says: "As the minimum lethal dose of the adder venom for an adult is probably 50 mg. and the amount injected by a British adder is between 5 and 10 mg., the results are seldom grave, but in small children and invalids energetic measures are called for." Apart from first aid, these measures should be directed to the treatment of vasomotor shock and relief of pain.

Nevertheless, in the first of the two cases here described it would have been a great comfort to be in a position to give intravenous antivenene on admission, for the boy seemed likely to die.

Spontaneous Expulsion through the Rectum of a Kocher Forceps left in the Abdomen 14 Months

I could not find, in the literature in my hands, a case similar to the one recorded below, so I thought it might be interesting enough to merit publication.

CASE HISTORY

A woman aged 40 was admitted to the county hospital on Dec. 30, 1943, complaining of the existence of a piece of scissors in her anus. 14 months previously she had been operated upon for a tumour of the uterus in a maternity hospital elsewhere. She was told that she had a large tumour of the uterus, which was removed. Except for a mild swelling on the left lower extremity no complication had occurred and the wound healed completely. The patient was discharged from the hospital 45 days after operation. At home she was quite well for about 8 months; then she began from time to time to feel pains in the left lower quadrant of the abdomen. Shortly after the onset of these pains she developed intermittent diarrhoea and vomiting. Some 20 days before attending hospital she felt a hard substance in her anus and was unable to crouch and sit. Finally, 17 days later, she touched a part of a pair of scissors which came to the mouth of the anus, and after working hard for two days succeeded in expelling it. She failed to extract the other part. The extracted piece proved to be a branch of a Kocher forceps.

Examination revealed a poorly nourished woman, semi-ambulant and appearing ill, with a temperature of 99.8° F. The pulse was 104. There was an operation scar in the midline between the umbilicus and the symphysis pubis. Vaginal examination revealed a freely movable cervix but no corpus luteum. The fornices were free of masses or infiltration; the patient's menses had ceased since operation. There was some slight tenderness and redness on the left side of the anus. On deep palpation rectally the other branch of the Kocher forceps could be felt; this was in an inclined position, so that the pointed end had plunged into the left ischio-rectal fossa. Under general anaesthesia the anus was dilated and the remaining branch of the forceps was extracted. After intervention the patient improved steadily and made a complete recovery.

The extracted piece was 14 cm. long, and formed a complete Kocher forceps with the part removed by the patient. Both pieces of this forceps were discoloured. After remaining 13 days under observation she was discharged home in excellent health.

COMMENT

A Kocher forceps left in the abdomen during a gynaecological laparotomy began to give rise to symptoms after nearly 8 months and travelled from the peritoneal cavity into the large intestine. The mechanism of this remarkable (and fortunate) migration is hard to explain. However, one may say with Jalaguier and Maclaure (1893) that first the foreign body encysted and some adhesion occurred with the intestine; this was accomplished in 8 months. Then under the protection of these adhesions the perforation of the intestine took place and the migration started: this phase lasted 6 months.

Reviews

CLINICAL SYPHILIS

A Synopsis of Clinical Syphilis. By James Kirby Howles, M.D., M.M.S. (Pp. 671; illustrated. 30s.) London: Henry Kimpton.

The appearance of this book is most opportune, partly because it is good on the whole, and partly because up-to-date monographs on syphilis are few. It is divided into three main sections: general considerations, systemic and regional syphilis, and familial and public health aspects. The first includes primary, secondary, latent, and tertiary syphilis, clinical and pathological diagnosis, treatment, and prognosis; the second, syphilis of the various organs and systems of the body, the treatment of each stage, organ, or system being given in the appropriate chapter. Section 3 is devoted mainly to congenital syphilis and syphilis in pregnancy; it includes the epidemiology of the disease and the organization of the syphilis clinic. In an appendix is a brief account of the history of the disease, and there is a long list of references.

The book is somewhat artificially arranged, but, as the author points out in his preface, the gain in clarity and the saving of space more than outweigh the obvious disadvantages. It can be said at once that, speaking broadly, this is a book which will be of great value to the syphilologist; it sets out the subject-matter with commendable clarity, experts are frequently quoted on debatable subjects, and there are numerous illustrations. Most of these are first-class, but some are hardly up to standard—e.g., Figs. 5, 6, and 9. Fig. 18, labelled "Pipestem lymphadenopathy [sic] of Dorsum of penis," shows what looks like a rather prominent dorsal vein, and Fig. 59 hardly represents what spirochaetes really look like under the dark-ground microscope; incidentally, it might have been useful if a more detailed account of how to set up and examine a dark-ground specimen had been included.

Here and there we find what seem to be rather important errors, such as (p. 152): "serologic test is of the greatest value from two weeks after the infection has occurred." Surely this should read, "after the appearance of the primary lesion." And on page 154, "report results as . . . doubtful (complete haemolysis)," should read, "incomplete haemolysis." In general the average reader would have been glad of a rather fuller section on false positive serum reactions. On page 256 occurs the word "seroprimary," which conveys to us no meaning at all; while on page 473 is the statement, "Organism (*Spirochaeta pallida*) . . . does not remain active, even under the most propitious conditions, for more than 48 hours"; this has been disproved by specimens which have crossed the Atlantic by ship several times and still retained their motility. These are a few shortcomings in an otherwise excellent account; it is the treatment described which lends itself most to criticism. Few modern syphilologists would agree with Plan A for early syphilis: why wait to start treatment till the first visit after the diagnosis; why not start at once, and why not start with an arsenical? On page 243 bismuth subsalicylate is described as oil-soluble, whereas on page 222 it is called a suspension, and the average weekly dose is 1 c.cm.—surely a very small one. The introduction of mercury rubs for early syphilis seems unconventional, and would hardly be necessary if the dosage of bismuth had been larger. No particular preference is shown for mapharsen over neoarsphenamine, but it is at least questionable if 0.01 g. of the former is equal to 0.1 g. of the latter in therapeutic effect; in the massive 5-day therapy it took 1.2 g. of mapharsen to produce as good results as 4.5 g. neoarsphenamine. It is of interest to note that for certain types of neurosyphilis Howles favours the Swift-Ellis treatment, one which many regard as *démodé*; and for non-specific protein therapy he gives his typhoid vaccine subcutaneously (p. 453); most people find the intravenous route more effective.

Taken as a whole this book gives an excellent account of the clinical picture, but the treatment recommended will not appeal to everyone; errors and omissions will, it is hoped, be corrected in a future edition. Nowadays, with syphilis so rife, what is wanted is an authoritative guide for the practitioner, and one which can be relied upon as correct in every detail.

AN ATLAS OF HUMAN ANATOMY

An Atlas of Anatomy By J. C. Boileau Grant, M.B., Ch.B., F.R.C.S. Ed. In two volumes. Vol. I. Upper limb, abdomen, perineum, pelvis, lower limb. Vol. II. Vertebral and vertebral column, thorax, head and neck. (Pp. 390, illustrated 55s. set of two volumes.) London: Baillière, Tindall and Cox, 1943.

This work in two volumes, and comprising a large number of original plates, has been produced by J. C. Boileau Grant, professor of anatomy in the University of Toronto, who, with the co-operation of a fine staff of dissectors, photographers, and artists, has provided an excellent pictorial record of human anatomy, which will be of great value to students, teachers, and practitioners, and will serve as a sure guide towards the acquisition of a clear mental picture of the chief anatomical features of the human body. Special methods have been employed for the sake of accuracy; these have involved the use of photographic films, and the making of tracings and enlargements of these, which have served as a basis for the "line" and "half-tone" drawings. Moreover, in many of the plates colours have been introduced, all important parts have been clearly labelled, and special observations noted in the form of captions.

Where many have taken part in the production of a composite work it is difficult to pick out anyone for particular commendation, but we would like to draw attention to the excellent half-tone drawings of Mrs. D. Chubb as being specially worthy of mention and as imparting a high artistic character to the work as a whole. The method which has been adopted of a uniform representation of parts drawn from the right half of the body only, so that successive figures may be easily compared, has the advantage which is claimed for it by the author. In practice, however, the surgeon has to deal with the left side as often as with the right, and the effort needed to recognize the change in the relative position of the parts on the two sides of the body is perhaps repaid by the equal familiarity which is gained from a visual knowledge, obtained by the haphazard (or, better, the systematic) study of both the right and left sides of the body. Thus a beginner, when examined on a part belonging to the opposite side of the body, to that which he has dissected and fixed his attention on, is often at a loss when confronted for the first time with a "looking-glass transposition" of the parts he is required to identify, and the same difficulty has to be overcome in the study of illustrations which are confined to one side.

Owing to careful revision there are very few errors which have escaped detection, and perhaps only one of these need be noted—namely, in Fig. 346 the adjectives "major" and "minor," with reference to the posterior rectus muscles of the occipital region have become transposed. The atlas as a whole is thoroughly reliable, and the author and his collaborators may be congratulated on the production of an anatomical work of very high standard and great utility.

A DOCTOR IN BURMA

Burma Surgeon By Gordon S. Seagrave (Pp. 159, illustrated 9s.) London: Victor Gollancz, 1944.

On the cover of this book there are quotations from two American reviews, saying—this is "one of the great stories of the war" and "a book filled with great deeds." Neither of these is an overstatement.

Dr. Seagrave was born and bred in Lower Burma and went to America for his medical education. While at Johns Hopkins he decided to become a medical missionary. He was of a very practical and resourceful nature, and one day, before he left the hospital, he noticed the operation-room attendant throwing away a basketful of broken-down surgical instruments, beyond repair. He asked if he might be given these castaways, and, as he says, "With them all my surgical work in Burma was done, for five years, in spite of the fact that they were broken and not mates—many of the haemostats would not remain clamped but would spring apart and permit large haemorrhages in the most embarrassing part of the operation." On arriving in Burma he was ordered to Nankham in Southern Burma. With his wife to help him he decided to build a hospital there, and with the aid of an old broken theodolite to survey the site of the hospital, which was to be built on a hill top, and the help of a missionary from Moulmein, and no previous experience in house construction, he produced his 100-bed hospital. As soon as the building was finished it filled

up rapidly, and continued to run to capacity. He says the most common diseases in the Shan States are, in sequence, malaria, gaitre, amoebic dysentery, gonorrhoea, and syphilis. He trained a staff of Burmese girls as nurses, and developed a large jungle practice, performing many major surgical operations.

The first half of the book is the story of an independent, self-reliant, and successful missionary doctor. Then came the war—the Battle of Burma—into which, with his staff of nurses and his equipment, he threw himself whole-heartedly. The Allied authorities at Rangoon gave him a number of trucks with which to carry on his medical work among the British, American, and Chinese troops in their retreat before the Japanese invasion. Then ensued months of peril and extreme hardship for them all. His loyal Burmese nurses were splendid all through. The cheery optimism of Dr. Seagrave was a constant encouragement to everyone. That his work was much appreciated is shown by the fact that he was promoted to the rank of lieutenant-colonel and awarded the Military Cross.

This book tells of almost incredible "deeds of derring-do," written in a modest matter-of-fact way. It contains much information about conditions in peace and war, of deep interest to medical men and the general public.

Notes on Books

It was in 1904 that Sir ROBERT HUTCHISON published in book form his *Lectures on Diseases of Children*, originally given to students of the London Hospital and those of us whose memories go back 40 years can well recall their eager first reading of this introduction to a subject which they knew to be important but which was sadly neglected in most general teaching hospitals. The book went through seven editions and eleven reprints in 32 years as the single-handed work of its author. For the eighth edition (1941) he entrusted the duty of revision to Dr. ALAN MONCRIEFF, who is responsible also for the ninth (Edward Arnold, 21s.). There was out-of-date matter to be pruned away and new work waiting to be grafted in. Dr. Moncrieff has handled the task with discretion and piety, leaving as much as possible of the original text while bringing it into line with recent advances in diagnosis and treatment. The principal changes are indicated in his preface. The result does him credit and assures this famous book a further period of useful life.

Treatment by Manipulation (H. K. Lewis and Co., 16s.) is the fourth edition of Mr. A. G. TIMBRELL FISHER's book originally published in 1925 under the title *Manipulative Surgery*. Notwithstanding the short interval since the third edition many changes have been made and some sections largely rewritten in the light of further experience and as the result of helpful criticisms, there are also a number of new illustrations of manipulative technique. In time of war manipulation acquires added importance because it so often enables disabled Service men or women, or the factory worker, to return to duty in the shortest possible time. It will also play a most important part in the treatment of many orthopaedic disabilities which, in spite of the great advances in treatment of wounds and injuries, will become a heavy charge upon the nation after the war.

"An international institution like the Red Cross at Geneva may receive from abroad an urgent request for antityphus vaccine and may hesitate whether to send the vaccine employed against enteric or that used against typhus fever." Typhoid fever has the Latin equivalent "typhus abdominalis," often shortened to "typhus" in Germany and some other countries. Because of such confusion in nomenclature the Joint Relief Committee of the International Red Cross asked at the end of 1942 for lists of terms denoting the various communicable diseases in different European languages, and Dr. YVES BIRAUD, whose experience in connexion with the League of Nations and the International Conference for the fifth revision of the Causes of Death fitted him admirably for the task, has prepared a *Polyglot Glossary of Communicable Diseases* to meet this need. After an introduction and an explanatory section, the disease names included in each successive international number 1 to 44 (infective and parasitic diseases), and communicable diseases occurring in other parts of the International List, are set out in columns comprising the 24 principal European languages, including Russian, Turkish, and Icelandic. Slav languages, using symbols derived from the Cyrillic alphabet, have been transposed phonetically (according to French pronunciation) into Latin characters, as indicated in a table. Many who use the *Glossary* will be grateful for this transliteration. An alphabetical index follows, referring each name to the international number in which it will be found and to the appropriate language column. For all who are interested in international medicine this work will be invaluable. It is published in London by Allen and Unwin at 4s.

LOCALIZATION IN THE CEREBRUM
AND CEREBELLUM

Understanding of the nature of the representation of function in the cerebral cortex was improved in the war of 1914-18 by a study of gunshot wounds in man. This study was mainly based upon careful clinical observation, unaided by the electrical tools which are available to-day. Between the two wars the study of the cortex was greatly helped, as Prof. E. D. Adrian points out in his Abrahams Lecture, printed in last week's *Journal*, by the development of electronics and by the production of barbiturate anaesthetics. The research which these advances have made possible led to a great increase in knowledge of the functions of the cortex of lower animals, and to an application of that knowledge to the understanding of functional representation in man described by Head, Holmes, Foerster, and others.¹ Experiments on man, carried out since by Foerster² and by Penfield,³ were largely confined to observing the results of stimulation of the motor and sensory areas of the cortex, and mapping out the areas of cortex which gave rise to characteristic responses. Animal experiments followed the same course—that of stimulation of small areas of cortex, which were carefully charted, and of observing the resulting peripheral activity, which might be the twitch of a limb, an apparently purposive movement, the response to a sensation, or an electrical discharge in a peripheral effector. An elaboration of this technique led to the long series of important experiments by Dusser de Barenne, who applied strychnine to minute areas of cortex. Before long the brain became mapped into an elaborate mosaic of functional areas, which often seemed to have an encouraging similarity to the cytoarchitectonic areas which had been described after histological studies by Brodmann⁴ and the Vogts.⁵

About a decade ago a most important change in experimental method occurred. People began to observe what happened in the cortex when peripheral end organs were stimulated. This was the result, of course, of the phenomenal development of thermionic-valve amplifiers, which were not available to earlier workers. It was encouraged, too, by the observation of the slow electrical changes which can so easily be recorded from the cortex, and which go to make up the electro-encephalogram. In 1933 Gerard, Marshall, and Saul⁶ found that displacement of a few hairs on the body surface caused a minute and sharply localized electrical change in the opposite cerebral

hemisphere. They pursued this observation and made a systematic study of the cortical changes which resulted from tiny stimuli in different parts of the body. The full results of observation of the cortical electrical potentials caused by lightly touching different parts of the monkey were published by Woolsey, Marshall, and Bard⁷ in 1942. In this paper they gave detailed maps of the cortical representation of touch. At the same time as this work was taking place in America Adrian was engaged in a similar investigation over here.⁸ He, also, found it possible to map out with great accuracy the cortical points where electrical potentials arose when different areas of skin were lightly stimulated. He drew up charts of the representation of touch in different animals. Some of the species differences are fascinating and throw light upon the way that the cortex deals with skin sensation. For instance, Adrian found that in the goat and the sheep most of the sensory cortex is concerned with messages received from the lips, the feet having a small cortical area, and the body hardly any at all, while the pig's snout has an enormous representation, area for area greater than that of the human hand, although the pig's body has no evident cortical representation at all. At the same time the spatial relationship of the cortical points subserving different areas of the body surface is constant, and, as Woolsey, Marshall, and Bard showed, is in general outline similar to that described from observation of human subjects. Nevertheless, although the excitable areas can be mapped with such accuracy, the representation of touch is as much functional as anatomical, since those areas of skin having the greatest application to the animal's mode of life had the greatest corresponding areas in the cortex.

The cortical representation of sensation does not take the form of an immutable, flat mosaic, where each nerve cell receives impulses from a single receptor or group of receptors. There is overlap between the skin areas represented, and there is electrical evidence of variations in the degree of response of single points from time to time. There is in fact the same kind of functional representation in the sensory cortex as Walshe⁹ has urged for the motor—a vital process of representation, in which the behaviour of each point is modified by its near or distant neighbouring points, according to the demands of the moment. Bard and his colleagues have shown that, although the dermatomes of the body can be charted in the sensory cortex by means of the electrical discharges which result from stimulation, they overlap greatly, rather in the same way as the tiles of a house. Although stimulation of a given area of skin may evoke with great readiness a response from a fixed and minute area of cortex, it can also evoke responses from a wider area. Both function and structure are represented together, for they are inseparable; but the anatomical representation is based not on the size but on the relative functional values of the skin areas concerned—or, in other words, on their innervation density. Similar investigations have been made upon the excitable cortex which subserves vision (Bartley and

¹ Head, H., *Studies in Neurology*, 1920, London.² *Lancet*, 1931, 2, 309.³ Penfield, W. G., and Boldrey, E., *Brain*, 1937, 60, 382.⁴ *Vergleichende Lokalisationslehre der Grosshirnrinde*, Leipzig, 1909.⁵ *J. Psychol. Neurol.*, Leipzig, 1919, 25, 279.⁶ *Proc. Soc. exp. Biol.*, N.Y., 1933, 30, 1123.⁷ *Johns Hosp. Bull.*, 1942, 70, 399.⁸ *J. Physiol.*, 1941, 100, 159; *Brain*, 1943, 66, 69; *Lancet*, 1943, 2, 13; *J. Neurophysiol.*, 1943, 6, 289.⁹ *Brain*, 1942, 65, 409.

Bishop¹⁰; Talbot and Marshall¹¹) and hearing (Bremer¹²; Galambos and Davis¹³), and, in general, similar results have been obtained, for specific stimuli cause nerve discharges in characteristically arranged points in the cortex. A sound of a given pitch affects one fibre; but if its intensity is increased it will affect another, and when the impulse, which is an ordinary nerve discharge, reaches the appropriate points in the cortex it gives rise to an electrical discharge which looks the same as those in the visual or somatic sensory areas. How the association areas of the brain change these similar impulses into different modes of sensation is another problem altogether. Prof. Adrian's fundamental work on the electrical activity and representation of function in the cortex of the cerebrum and cerebellum is rapidly falling into line with similar work from several laboratories in America, some of which has been quoted. It is forming a basis for such a great advance in knowledge that, in his own words, "it is difficult to foresee how far it may not go."

EPIDEMIOLOGY AND EVACUATION

After the outbreak of war large numbers of children were evacuated from areas exposed to bombing; although many returned within a few months there was another outward movement when, in 1940-1, bombing began on a large scale. From May, 1941, until 1944 the danger was not acute in the great cities; it has only become so since flying bombs began to be launched, and mainly affects London and other built-up areas in the south of England. The scale of the new exodus is large, and it is of interest to summarize the epidemiological results of the earlier movement. On general principles it was to be expected that the movement of town children into the country or smaller towns, associated as it was with the complete or partial closure of schools in the target area, would lower the incidence of the infectious diseases of children in the target areas and raise the incidence upon children in the reception areas. To test this hypothesis required a mass of detailed information not accessible to private students, but fortunately Dr. Percy Stocks of the General Register Office was permitted to publish in the *Journal of the Royal Statistical Society*¹⁴ two papers giving a complete view of the facts; these papers, supplemented to some extent by contributions to the discussions from various experts, are the most important contribution to pure epidemiology in England and Wales the war has produced. It may be said at once that expectation was justified. To take a single illustration: in the administrative county of London the incidence rate of diphtheria in the fourth quarter of 1939 was a third less than that of the second quarter; in great towns which were reception areas the estimated increase of the incidence rate varied from a rise of 9% to one of 122%, with an average of 73%. A point of interest was that, if reception areas were classified by the ratio of immigrant children to resident children,

the increased incidence on the latter did not increase *pari passu* with the ratio. A possible explanation, partly supported by evidence given in the discussion, would be that the intimacy of commingling of the visiting and resident children did not increase as the number of the former; for example, there might be separate use of schools when the numbers justified this. One has a parallel in experimental epidemiology in which the problem was studied, as it were, in reverse, susceptibles being added to an infective population. It was found that regular small accessions had on the whole a greater effect in keeping up mortality than sudden large accessions.

What was true of diphtheria and scarlet fever was, in a general way, true of measles and whooping-cough. In measles there was evidence that epidemics which had been expected in evacuation areas were delayed; the epidemic expected in London was three or four quarters late, and there was a lesser delay in Liverpool, Sheffield, and Manchester. In view of the fact that in New York an expected epidemic in 1940 was also three quarters late, although there was no evacuation, there was some discussion whether the obvious explanation—viz., that a reduction in the proportion of susceptibles in the population had broken the periodicity—could be accepted, and the hypothesis of Brownlee which gave weight to a possible mutation of the *materies morbi* was canvassed. On the whole speakers favoured the view that evacuation was the prime cause, and that school closure in the target areas was an important link in the chain of factors making for reduction of means of transferring infection. During the months of heavy night bombing there was great congestion in some places of safety, but the unfavourable effect of this was more than offset by the outward movement of juvenile population.

We have mentioned only a few general results. The two papers contain detailed analyses which should be studied and data which enable other students to investigate matters not discussed. Under our new calamity, outward movement began approximately a month sooner than in 1939; how long it will continue and its ultimate volume are not within our powers of reasonable conjecture. Assuming a similarity of conditions, we should, however, expect that the epidemiological results will conform to those of 1939-40.

THE QUESTIONARY

The answers to the Questionary on the White Paper, prepared at the request of the B.M.A. by the British Institute of Public Opinion, have now been sifted and analysed by the Institute, and the results are published in this week's *Supplement*. No doubt they will be interpreted variously by different people according to their predilections. Clearly there are limitations to this method of inquiry, which, according to a well-known Public Relations Officer, Mr. E. Rawdon Smith, is "rather like taking the patient's temperature and relying only upon that for a diagnosis."¹ But, within its limitations, the analysis affords a guide to trends of opinion within the profession, and within different groups of the profession. Some critics have committed themselves in advance. Prof. Major Greenwood has thrown doubts on the fitness of the Questionary to

¹⁰ *Amer. J. Physiol.*, 1933, 103, 159.

¹¹ *Amer. J. Ophthalmol.*, 1941, 24, 1255.

¹² *C. r. Soc. Biol. Paris*, 1938, 130, 257.

¹³ *J. Neurophysiol.*, 1943, 6, 39.

¹⁴ *J. roy. Statistical Soc.*, 1941, 104, 311; 1942, 105, 259.

obtain objective answers to questions on the White Paper, stating: "On the assumption that an unbiased opinion given by persons who had read the White Paper was desired, the Questionary is bad."² Dr. D. G. Leys and Dr. Horace Joules challenged the validity of the Questionary thus: "Unfortunately the B.M.A., in obtaining the services of the British Institute of Public Opinion, casts a cloak of impartiality over what is in fact a tendentious document. To many doctors some of the questions as put will be unanswerable, since they are framed neither upon general principles nor Government policy, but upon the policy of a section of the profession only, and, moreover, a policy which represents a considerable retreat from the relatively forward-looking programme established by the Planning Commission set up by the B.M.A. itself in 1942."³ For the most part the Questionary was answered and sent in within a few weeks of publication of the White Paper. The small return of answers from men in the Services is to be noted.

The Questionary was sent to 53,728 medical men and women, and replies have been received from 25,435, this apparently constituting a "world record" for an inquiry of this nature. Answering the general question "Are your reactions to the White Paper favourable?" 53% said "No"; and, although 40% assessed their reactions to the White Paper as favourable, only 32% believed that the introduction of a National Health Service would enhance "the quality of the country's medical service." On what is called the "100% issue," 60% of all groups supported the White Paper proposal that the National Health Service should include everyone: it is worthy of note that 54% of the consultants and 54% of the general practitioners voted in this way. Fifty-five per cent. agreed that the general practitioner should be under contract with a Central Medical Board, and 68% approved the principle of health centres: of the general practitioners 59% approved and 32% disapproved of health centres; but 63% of G.P.s disagreed with the proposal that doctors working from health centres should have a joint contract with the C.M.B. and the local authority owning the health centre. Question 17 asked: "Bearing in mind that 'the doctor practising in a centre will not be debarred from private practice outside it,' what method of remuneration would you like to see adopted for doctors working in health centres?" Twenty-eight per cent. of all answering were for payment by salary; 34% favoured a small basic salary plus capitation fees; 23% voted for payment by capitation fees; and 6% wanted to have capitation fees pooled. For payment in separate practices a still smaller percentage wanted payment by salary, and the majority preferred capitation fee.

Some points of interest arise in the replies to questions on administration. For example, 91% believe that the Central Health Services Council should have the right to publish an annual report, and also the right to publish advice at its own discretion; 76% regard the proposed composition of the Joint Boards as unsatisfactory, and 80% "I like to see doctors and other health workers directly represented on the Joint Boards. The B.M.A.'s Principle D stated: "The profession rejects any proposal for the control of the future medical service by local authorities as at present constituted": 80% of all groups considered that the White Paper infringes this principle. The proposed power of the C.M.B. to prevent doctors starting public practice in an over-doctored area was viewed favourably by 57%; but 66% objected to the power of the C.M.B. "to require the young doctor during the early years of his career to give his full time to the

public service where the needs of the service require this." The answers to the question (9a) on central administration showed, according to the B.I.P.O., that many doctors feared that the medical profession would come under political control.

These are just some of the points; for the rest readers should turn to this week's *Supplement*.

PENICILLIN PRODUCTION

Until recently penicillin was available in so small an amount as to be for most people a medical curiosity; only a few isolated patients were able to benefit by it. Another series of papers in this week's *Journal* provides further evidence of the tremendous strides made by the pharmaceutical industry, which is now putting penicillin at the disposal of medical men working in widely varying fields. For these supplies we are largely indebted to our American friends, who have won the third victory in the penicillin field. The first was Fleming's discovery; the second was the victory of Florey and his colleagues, who showed how to obtain penicillin in relatively pure form, and who demonstrated its clinical use. There remained a third problem—to produce it on a large scale. It is this problem which the Americans have solved, and we owe much to their foresight, energy, and correct estimation of the magnitude of the effort required. The credit for the supplies of penicillin is chiefly due to Dr. A. N. Richards, the chairman of the Committee for Medical Research, one section of the Office of Emergency Management in which President Roosevelt develops his measures for prosecuting the war. Dr. Richards, formerly professor of pharmacology at the University of Pennsylvania, is well known to workers on renal physiology. He devised the method of withdrawing fluid for examination from the renal tubule. As chairman of the Committee for Medical Research his main concern was with research and not with production, and he might well have taken the view that the question of the supply of penicillin was no affair of his. Nevertheless he seems to have realized, when Florey took the news of his findings to Washington late in 1941, that here was a question on which the pharmaceutical manufacturers required guidance and encouragement. Dr. Richards must have taken a heavy load of responsibility on his shoulders in recommending the enormous outlay on plant necessary to make the present supply of penicillin possible. Yet he took this responsibility in face of the chance that at any moment a synthetic process would render obsolete the plant for growing the mould. The synthesis of penicillin by a method practicable on a large scale has not yet been achieved, and so Dr. Richards has the reward of knowing that as a result of his effort the lives of very many American and British wounded are being saved every day. We can acknowledge this debt to the U.S.A. without in any way disparaging the efforts which have been made to the same end in this country. British manufacturers, although hampered by a far greater shortage of material and labour, furnished most of the penicillin which has been used by Army casualties in the Mediterranean theatre of war, and for research purposes in this country, and are now contributing to available stocks on an increasing scale.

RESEARCH IN OPHTHALMOLOGY

We announce elsewhere in this issue the decision of the Council of the Royal Eye Hospital to establish an Institute of Ophthalmology—a decision that will, we hope, bear fruit in an advance of knowledge in this important branch of medicine. It is substantially true that medical research

² *Lancet*, April 1, 1944, p. 451.

³ *Ibid*, April 8, 1944, p. 486.

in this country is still very largely a matter of individual effort. Research "foci" rather than research "centres" have tended to develop. By good fortune it has happened that occasionally a tradition for research has centred at a particular hospital for more than one generation, but more often the passing of an outstanding figure has also meant the decline of the particular focus from prominence. In recent articles in this *Journal* stress has been laid upon the man rather than the organization. This thesis was eloquently stated by Dr F M R Walshe,¹ and has been elaborated in relation to ophthalmology by Sir John Parsons.² Dr C G Kay Sharp,³ pointing out that "planning for research" and "planning of research" are not synonymous, has stressed the need for organized facilities through which the individual worker can express himself. The distinction made by Dr Kay Sharp is not unimportant, and it is mainly owing to his initiative that the planning for ophthalmic research has become a reality. Some six years ago in a letter in these columns⁴ he stressed the need for national planning in the prevention of eye disease, and advocated that in the first place the local authorities, who jointly spend over £2,000,000 annually for the welfare of the blind, should set aside 1% of this expenditure to establish a central research fund, and, secondly, that some four research centres be set up in closest co-operation with existing ophthalmic centres—one in the North of England, one in the Midlands, and two in London.

It is gratifying to record that a move in this direction is now being made. The County Councils Association and the Association of Municipal Corporations have agreed, on the recommendation of their Joint Blind Welfare Committee, that a sum at present estimated at about £20,000 ought to be provided annually by the county and county borough councils to subsidize planned and co-ordinated research. The associations also foresee the establishment of a National Ophthalmic Research Council to administer the proposed funds, and it is contemplated that in the first instance five research centres should receive subsidies according to their need. This scheme is to be submitted to the Ministry of Health, and, later, the necessary concurrence of the individual county and county borough councils will be sought. Two research centres have come into existence since Dr Kay Sharp's letter of 1938—one at Oxford and the other the research unit at the Royal Eye Hospital. The pioneer efforts of both these centres amply justify support

MALARIA CONTROL IN NORTH-EASTERN INDIA

The report of the Committee of Control of the Indian Branch of the Ross Institute of Tropical Hygiene for the year ending June 31, 1942, was reviewed some little time ago in this *Journal*. Regarding the general tenor of the report for 1943 little need be added to what was said in our review of its predecessor. But one important feature should be mentioned—viz., that with the report for 1943 is incorporated a summary of the principles underlying malaria control in India, with special reference to the North-Eastern Frontier. This was drawn up by Dr G C Ramsay and incorporated in the report to meet requests by several military medical officers for copies of Dr Ramsay's publications. Since Dr Ramsay's experience of anti-malaria work in North Eastern India must be unique, this brief but excellently condensed conspectus of possible methods of malaria control has additional interest now that the part of India to which it refers has come

so prominently into the war picture. Starting with a brief account of the breeding-places of *A. minimus*, the chief carrier in North-East India, Dr Ramsay deals serially with stream training, oiling, paris green, cuprous cyanide as a larvicide, water pollution as an antilarval measure, and control of breeding in kutchha wells. These are all classed as temporary measures. The permanent measures, which should replace temporary ones whenever possible, are site selection, provision or preservation of dense shade over water channels, flushing, drainage, flooding, subsoil methods, fascine drainage, concrete inverts, vertical drainage, flooding, control of irrigation, filling, and zooprophyllaxis. Notes on *A. sin laicus* and *A. philippinensis*, which are important under certain conditions, and on biological methods are also added. Under these heads are given in a few words the relevant and salient points about each, altogether an excellently informed review of measures adapted to this region of India. In appendices to the report the long list of firms and other subscribers to the Indian Branch testifies to the success of this co-operative scheme for improvement of health on estates and other labour employing concerns which has been initiated and ably carried out under the Ross Institute.

MINERS' DISEASES IN THE PAST

Thousands of years ago men were delving into the earth to find the raw materials on which ancient civilization depended for its existence. After the stage of primitive surface mining had passed, underground mining produced a surplus of materials which exceeded the needs of the few who owned the mines. So mines became a source of great wealth, while the miners, who were slaves or prisoners or criminals sent underground to expiate crime, toiled in the stifling stench and produced the wealth desired by society. The almost complete disregard of the miner and his diseases by ancient medical authors expresses the social indifference to the industrial worker of those times. Later studies by physicians of the Middle Ages, particularly Agricola and Paracelsus, and the periods which followed up to the end of the nineteenth century showed the increasing interest taken by the medical profession in industrial diseases. But while physicians proposed various preventive measures they were in no position to make them effective. Any improvements made in mining conditions came as a result of technical advances in engineering and of Acts of Parliament, which were the products of public opinion and nineteenth-century trade unionism rather than the fruits of medical research. These Acts were designed primarily to prevent the catastrophic explosions which inflicted great loss of life and the exploitation of women and children underground. Nevertheless they did exert a salutary effect on the health of mine workers. In his recent monograph¹ Dr George Rosen has given a historical analysis of one industry which shows clearly the factors that retard or accelerate the development of an industrial society. Those who are interested in the application of medical science to social problems should read it, because from the past there are lessons to be learnt for the future. It is probably the first document of its kind to show so clearly that the prevention of disease among workpeople must be the collective responsibility of society, and that our profession acting alone can achieve very little even with special knowledge of the relation between work and health. The author finishes his story at the end of the nineteenth century. May he fulfil his hope to tell the more recent history of diseases among miners in a companion work.

REGISTRATION OF SPECIALISTS

THE G.M.C. ASKS FOR LEGISLATION

The General Medical Council, sitting *in camera* at its recent May session, approved a report with recommendations from a special committee which has been considering the registration of specialists. This committee, under the chairmanship of Prof. Sydney Smith, and with Dr. H. Guy Dain as one of its members, was appointed in November, 1943, to report on the steps which should be taken by the Council concerning the admission of specialists to a statutory register. It was asked to consider the conditions of admission both during and after an interim period, the conditions under which postgraduate qualifications might be held to deserve recognition, and the postgraduate experience which might be regarded as enabling a practitioner to be registered as a specialist.

The History of the Matter

Proposals for a register of specialists had already been made. One such appears in the draft interim report of the Medical Planning Commission, which calls for an authoritative committee to determine the standards conferring consultant status. The White Paper spoke of the need for more consultants and a better distribution of them, adding that one of the aims of the proposed National Health Service would be to encourage more doctors of the right type to enter this branch of medicine or surgery and to provide the means for their training. The White Paper, however, stopped short of proposing in detail a form of consultant service,¹ and stated that the Government was awaiting the report of Sir William Goodenough's Committee on Medical Schools. That report was published a fortnight ago (*Journal*, July 22, p. 121).

In the House of Commons in February last the Minister of Health announced that local lists of practitioners who fulfilled certain conditions of admission to a specialists' register were being compiled by Area Committees under the supervision of the Central Medical Academic Council. This Council is a body set up by the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Royal College of Obstetricians and Gynaecologists, and in addition to representatives of the Colleges includes representatives of the British Medical Association and of the eleven universities in England and Wales which are licensing bodies. The Area Committees cover England and Wales in eleven regions, of each of which a university is the centre, and the membership includes the vice-chancellor, the dean of the faculty of medicine, and representatives of consultants and general practitioners. Local lists in Scotland have also been compiled, but by a different method.

The criterion for inclusion in the specialists' list during the interim period, for immediate administration purposes, is that the practitioner has acted as a specialist in the past and is generally recognized as a specialist by other practitioners in the area where he practises. No doubt after the interim period some more closely determined conditions will be laid down for admission, as, for example, training at an approved hospital, a minimum period of experience, the possession of a higher degree or diploma, the holding of a recognized appointment, and an undertaking not to engage in general practice. The General Medical Council committee, however, has not yet determined what it calls the "future consultant (or specialist) status," and has so far dealt only with the interim status. In February last, while its committee was still engaged on this work, the Council reaffirmed its view that in the public interest it was desirable that a statutory register of specialists should be formed and maintained by the Council and that the conditions of admission to such a register during the interim period should be those just stated—namely, that the practitioner had acted as a specialist and was recognized as such by other practitioners in his area.

The immediate or interim purpose of such a register of specialists would be to provide the Government and the municipal and participating voluntary hospitals—i.e., the

authorities responsible for organizing a service of specialists as part of the National Health Service—with an authoritative and convenient means of ascertaining whether a particular practitioner is eligible to hold such an appointment. It follows that the register must be available at a date not later than that on which a service of specialists may be inaugurated as part of the National Health Service outlined in the White Paper.

On the recommendation, therefore, of its special committee the General Medical Council has resolved to represent forthwith to the Privy Council that legislation be introduced empowering the Council to make and maintain a register of specialists, such register to be available not later than the date of commencement of the service.

The Form of the Register

The next question to which the committee of the G.M.C. addressed itself was the form which such a register should take. Should it be a book separate from the *Medical Register*, or an appended list forming part of the *Medical Register* itself; or should there be a separate column in the *Medical Register* to denote a specialist, or use be made of the fourth column—the one headed "Qualifications"—for this purpose? All these methods have their advantages and disadvantages. One disadvantage of a separate book—although, to be sure, it applies in some degree to the other methods, for the *Medical Register* is in many public libraries—is that it would be accessible to lay people who believed themselves competent to choose specialists.

In the end the committee decided that the procedure should be to insert the word "Specialty" or "Specialties" opposite the name of the practitioner in the column headed "Qualifications" in the existing *Medical Register*, and to add the subject or subjects in which he had been recognized by the Council as a specialist, with the year of his recognition. Further, for facility of reference, it was decided that the *Medical Register* should contain an alphabetical list of specialties with, underneath each heading, the registered names of the recognized practitioners, again given alphabetically. From this it would be possible to refer to the full particulars of the practitioner given in the main body of the *Medical Register*.

When the Minister of Health, as mentioned above, informed the House of Commons that local lists were being compiled, he made a clear distinction between the restrictions to be placed on the use of the local lists so long as provision is not made by legislation for the establishment of a register of specialists and the freedom of Parliament to determine the manner in which a statutory register should eventually be set up. His words are worthy of quotation:

"I am, therefore, glad of this opportunity of assuring the profession, and especially its members who are on war service at home or abroad, that such lists will be treated as strictly confidential and will not be used as a test of eligibility for appointment as consultant or specialist in any comprehensive post-war hospital service. If, at a later date, it were thought desirable that consultant and specialist appointments should be restricted to persons qualified in some particular manner and enrolled on a list for the purpose, it would be necessary to provide for the establishment of a register on a statutory basis in a manner approved by Parliament."

The sense of the General Medical Council's discussions on this point is that it is neither necessary nor desirable for the Council to repeat or to revise the work of the Central Medical Academic Council (set up by the Royal Colleges) or of its Area Committees in preparing the local lists for England and Wales, and no doubt the same view would be taken concerning the local lists in Scotland. It is assumed that these local lists are based upon the knowledge of competent authorities of the subject or subjects in which each registered medical practitioner included in the lists is accepted as a specialist.

The recommendation of the committee, accepted by the G.M.C., is that the legislation to empower the Council to form and maintain a register should confer the right of admission to the register upon (1) practitioners on war service abroad whose names are included in any list of specialists, compiled before an appointed day, which appears to the Council to deserve recognition in the register, and (2) practitioners whose names are included in any such list on the ground that they

¹ In the White Paper the terms "consultant" and "specialist" are used as alternatives or as complementary to each other. In the General Medical Council report the word "specialist" is generally used.

FOR MYCOTIC INFECTIONS OF THE SKIN

○ Ringworm of the groin and axillae, athlete's foot—common infections of the skin—are spread more easily under conditions of communal living where contact between large numbers in camps, billets, reception areas is more likely to be close and cross infection therefore greater.

Moreover, the healthy indulgence in sports wherever possible these days unfortunately may, in dressing rooms, through infected mats and towels,

provide scope for contact and infection

'Mersagel' contains phenylmercuric acetate—an extremely powerful fungicide—incorporated in a jelly base. Lightly rubbed into the affected part, be it between the toes or in the creases of the groin, or between the folds of the axilla, and then covered with gauze or lint, 'Mersagel' rapidly clears up acute infections after a few applications.

'Mersagel' can also be used prophylactically among contacts

AVOID- your Patient's Cold...

A pleasant way of preventing infection from patients suffering from colds is the timely application of 'Endrine.'

A few drops sniffed up each nostril will avoid the discomforts of nasal congestion and the chance that you yourself will infect your patients.

'Endrine,' with its carefully selected ingredients and well-balanced formula, acts as a mild astringent, and by reducing nasal congestion promotes sinus drainage and improves breathing.

—this word has, in these difficult times, a new significance, particularly to those deaf persons enabled by the use of a trustworthy hearing aid to "do their bit" in the war effort.

To people already using aids to hearing we offer the resources of our Service Department to keep those aids in good order and to make essential replacements. Whether the aids were originally supplied by us or not, we shall be happy to do all we can to help their users in obtaining the greatest possible satisfaction and efficiency.

For patients who really need hearing aids of high quality, our testing and fitting services are still available, together with the after-sale service that has made BONOCHORD so popular.

The BONOCHORD Hearing-Aid Service is available to all interested in better hearing. We invite you to use it whenever necessary. Full details on request.

EVARSAN

Neoarsphenamine (Evans)

Progressive research at The Evans Biological Institute has yielded a highly purified neoarsphenamine of exceptional quality.

Batch Uniformity

Evarsan shows uniformity in chemical and biological properties from batch to batch.

Low Toxicity

Animal tests show that the toxicity is at least nineteen per cent lower than the official minimum requirements for neoarsphenamine.

Manufactured and tested under U.K.
Manufacturing Licence No 18

High Therapeutic Activity

Despite low toxicity, therapeutic activity is maintained at a high level and for most batches is about fifteen per cent. higher than the official minimum requirements.

Stability

Evarsan exhibits a high degree of stability.

Approved by the Ministry of Health for
use in Venereal Disease Clinics.

Full details of the use of Evarsan and other Evans products in the treatment of syphilis are contained in a handy pocket book "The Treatment of Syphilis" free on request to:
Liverpool: - - - Home Medical Dept, Speke, Liverpool, 19.
London: - - - Home Medical Dept, Bartholomew Close, E.C.1.

have acted as specialists in the past and are generally recognized as such by other practitioners in their areas. The same legislation should confer the right upon any other practitioner to make an application for admission, and should empower the GMC to make regulations prescribing the way in which applications are to be made and determined.

Future Registration

When, therefore, the service of specialists comes into operation the Government and the hospitals will have available an interim statutory register, first in the form of a series of entries in the *Medical Register* indicating that the practitioners have been recognized by the General Medical Council as specialists in a stated subject or subjects, and also a separate list of specialties with the names of practitioners following. This, however, leaves much to be considered. In the view of the committee the object of a statutory register of specialists kept by the GMC would be to establish and maintain a standard of postgraduate medical qualification and experience such as would guarantee that practitioners who had attained that standard could properly be recognized in the register as specialists. Many, of course, by any standard will be recognized as possessing consultant (or specialist) status, which is valid not only for the interim but for the future period. But questions of some difficulty will arise. It is generally agreed for example, that specialist status should in future imply the possession not only of postgraduate qualifications but of postgraduate experience, but are such qualifications to be regarded as indispensable for the practice of all registrable specialties, and, so far as they are indispensable, what is the value in relation to specialist status of postgraduate qualifications in medicine, surgery, and midwifery and the postgraduate qualifications in specialties now granted by the licensing bodies? What should be the nature and the duration of the postgraduate experience demanded in each registrable specialty? How far should the powers of the Council to register postgraduate qualifications be extended by legislation? Should provision be made for the Council to consult appropriate professional bodies about the conditions of admission to the register after its initial formation?

This GMC report was issued before the Goodenough Committee's report appeared, and it is expected that the further work of the GMC committee will be much facilitated by perusal of the Goodenough report, especially the section on postgraduate training and experience for intending specialists. It is intended to make a further report to the Council in the light of the Goodenough recommendations as soon as possible.

BEIT MEMORIAL FELLOWSHIPS

The Trustees of the Beit Memorial Fellowships for Medical Research in their annual report for the year 1943-4 state that they accepted with great regret the resignation of Prof T R Elliott FRS, who had been secretary to the advisory board since 1930 and whose experience and wisdom had been of inestimable value. His place on the board had been taken by Sir Thomas Lewis, M.D., FRS, and Dr A N Drury, FRS, had been appointed acting secretary.

The following elections were made with permission for each Fellow to be seconded at any time for war duties.

Fourth year Fellowships (£500 a year)—W Holmes, M.A., D.Phil. to continue the study of the regeneration of nerve fibres after injury, at the Department of Zoology and Comparative Anatomy, University Museum, Oxford. Mary F Locket, M.D., M.R.C.P. to continue the study of renal pressor substances responsible for experimental high blood pressure, at the Pharmacology Laboratory, Cambridge.

Junior Fellowships (£400 a year)—J C Boursnell, Ph.D. to study the fate and functions of trace and some other elements in the animal body using radio-active isotopes, at the Department of Biochemistry and Chemistry, the Medical College of St Bartholomew's Hospital. G A Levy, Ph.D., D.Sc. to study the adaptive enzymes in the animal body with special reference to the role of glucuronidase in the metabolism of steroid hormones and related substances, at the Department of Medical Chemistry, University of Edinburgh. H J Rogers, Ph.D. to study the biochemistry of

hyaluronidase obtained from various sources, and the role of enzymes such as hyaluronidase and leucithinase and other bacterial antigens in infection, at the Lister Institute, Elstree, Herts. G J Romanes, Ph.D., M.B., B.Ch. to study the relationship between the developing mesoderm and the motor apparatus of the spinal cord supplying it, at the Department of Anatomy, University of Cambridge. F Sanger, B.A., Ph.D. to study the chemical structure of proteins, with special reference to insulin, at the Sir William Dunn Institute of Biochemistry, Cambridge. S P V Sherlock, M.B., Ch.B., M.R.C.P. to study the hepatic function in disease by biopsy methods, at the Department of Medicine, British Postgraduate Medical School, C Weymouth, Ph.D. to study the factors influencing tissue growth *in vitro*, at the Physiology Department, University of Aberdeen. E C Webb, B.A. to study the ultimate mode of action of drugs and poisons in living tissues, at the Sir William Dunn Institute of Biochemistry, Cambridge.

SCIENCE FELLOWSHIPS FOR BRITISH UNIVERSITIES

The Directors of Imperial Chemical Industries have offered to provide at nine British universities a total of 80 Fellowships to be held by senior workers in certain branches of science—namely, physics, chemistry, and the sciences dependent thereon, including chemotherapy. The Fellowships will be of the average value of £600 per annum and the scheme will operate for an initial period of seven years. The Directors of ICI have described on broad lines the subjects in which the Fellowships are to be held, but the administration of the scheme rests wholly with the universities and no conditions are attached by the directors to their tenure. The Fellows will be members of the university staffs and will be concerned only with the duties laid upon them by the universities. Their primary work will lie in research, but they will also, it is hoped, take some part in university teaching. Oxford, Cambridge, and London have each been offered 12 Fellowships, Glasgow, Edinburgh, Liverpool, Manchester, and Birmingham, 8 each, and Durham 4. It is hoped that by this policy there will emerge a body of men capable of taking high academic or industrial positions thereby advancing academic research and industrial research, which in the view of ICI are indivisible and interdependent.

INSTITUTE FOR RESEARCH AND TEACHING IN OPHTHALMOLOGY

The Council of the Royal Eye Hospital has decided to establish an Institute of Ophthalmology where teaching and research can be carried out systematically and co-ordinated with the work of laboratories and of other ophthalmic and of general hospitals. The Institute, with an independent board of governors, will work under the patronage of the Archbishop of Canterbury, the Archbishop of Westminster, the Very Rev Cyril Golding Bird, General Sir Bernard Montgomery, and Sir Philip Henriques, and under the presidency of Admiral Sir Edward Evans. A board of governors is being constituted with Mr James Cadman as treasurer and chairman of the Finance Committee. To ensure that the Institute is broadly based, panels of advisers have been set up to help in the planning and carrying out of the work.
